The UI structural components rely on personalization and provide the core structure and services needed by all Web Parts controls. One UI structural component required on every Web Parts page is the WebPartManager control. Although never visible, this control has the critical task of coordinating all Web Parts controls on a page. For example, it tracks all the individual Web Parts controls. It manages Web Parts zones (regions that contain Web Parts controls on a page), and which controls are in which zones. It also tracks and controls the different display modes a page can be in, such as browse,connect, edit, or catalog mode, and whether personalization changes apply to all users or to individual users. Finally, it initiates and tracks connections and communication between Web Parts controls.

The second kind of UI structural component is the zone. Zones act as layout managers on a Web Parts page. They contain and organize controls that derive from the Part class (part controls), and provide the ability to do modular page layout in either horizontal or vertical orientation. Zones also offer common and consistent UI elements (such as header and footer style, title, border style, action buttons, and so on) for each control they contain; these common elements are known as the chrome of a control. Several specialized types of zones are used in the different display modes and with various controls. The different types of zones are described in the Web Parts Essential Controls section below.

The Web Parts UI controls, all of which derive from the **Part** class, comprise the primary UI on a Web Parts page. The Web Parts control set is flexible and inclusive in the options it gives you for creating part controls. In addition to creating your own custom Web Parts controls, you can also use existing ASP.NET server controls, user controls, or custom server controls as Web Parts controls. The essential controls that are most commonly used for creating Web Parts pages are described in the next section.

Web Parts Essential Controls

The Web Parts control set is extensive, but some controls are essential either because they are required for Web Parts to work, or because they are the controls most frequently used on Web Parts pages. As you begin using Web Parts and creating basic Web Parts pages, it is helpful to be familiar with the essential Web Parts controls described in the following table.

WEB PARTS CONTROL	DESCRIPTION
WebPartManager	Manages all Web Parts controls on a page. One (and only one) **WebPartManager** control is required for every Web Parts page.
CatalogZone	Contains CatalogPart controls. Use this zone to create a catalog of Web Parts controls from which users can select controls to add to a page.
EditorZone	Contains EditorPart controls. Use this zone to enable users to edit and personalize Web Parts controls on a page.
WebPartZone	Contains and provides overall layout for the WebPart controls that compose the main UI of a page. Use this zone whenever you create pages with Web Parts controls. Pages can contain one or more zones.
ConnectionsZone	Contains WebPartConnection controls, and provides a UI for managing connections.

WEB PARTS CONTROL	DESCRIPTION
WebPart (GenericWebPart)	Renders the primary UI; most Web Parts UI controls fall into this category. For maximum programmatic control, you can create custom Web Parts controls that derive from the base **WebPart** control. You can also use existing server controls, user controls, or custom controls as Web Parts controls. Whenever any of these controls are placed in a zone, the **WebPartManager** control automatically wraps them with **GenericWebPart** controls at run time so that you can use them with Web Parts functionality.
CatalogPart	Contains a list of available Web Parts controls that users can add to the page.
WebPartConnection	Creates a connection between two Web Parts controls on a page. The connection defines one of the Web Parts controls as a provider (of data), and the other as a consumer.
EditorPart	Serves as the base class for the specialized editor controls.
EditorPart controls (AppearanceEditorPart, LayoutEditorPart, BehaviorEditorPart, and PropertyGridEditorPart)	Allow users to personalize various aspects of Web Parts UI controls on a page

Lab: Create a Web Part Page

In this lab, you will create a Web part page that will persist information via ASP.NET profiles.

Creating a Simple Page with Web Parts

In this part of the walkthrough, you create a page that uses Web Parts controls to show static content. The first step in working with Web Parts is to create a page with two required structural elements. First, a Web parts page needs a WebPartManager control to track and coordinate all Web Parts controls. Second, a Web Parts page needs one or more zones, which are composite controls that contain WebPart or other server controls and occupy a specified region of a page.

> **NOTE**
> You do not need to do anything to enable Web Parts personalization; it is enabled by default for the Web Parts control set. When you first run a Web Parts page on a site, ASP.NET sets up a default personalization provider to store user personalization settings. For more information about personalization, see Web Parts Personalization Overview.

To create a page for containing Web Parts controls

1. Close the default page and add a new page to the site named WebPartsDemo.aspx.
2. Switch to **Design** view.
3. From the **View** menu, make sure that the **Non-Visual Controls** and **Details** options are selected so you can see layout tags and controls that do not have a UI.
4. Place the insertion point before the `<div>` tags on the design surface, and press ENTER to add a new line. Position the insertion point before the new line character, click the **Block Format** drop-down list control on the menu, and select the **Heading 1** option. In the heading, add the text **Web Parts Demonstration Page**.
5. From the **WebParts** tab of the Toolbox, drag a **WebPartManager** control onto the page, positioning it just after the new line character and before the `<div>` tags.

The **WebPartManager** control does not render any output, so it appears as a grey box on the designer surface.

6. Position the insertion point within the `<div>` tags.

7. In the **Layout** menu, click **Insert Table**, and create a new table that has one row and three columns. Click the **Cell Properties** button, select **top** from the **Vertical align** drop-down list, click **OK**, and click **OK** again to create the table.

8. Drag a WebPartZone control into the left table column. Right-click the **WebPartZone** control, choose **Properties**, and set the following properties:

   ID: SidebarZone

   HeaderText: Sidebar

9. Drag a second **WebPartZone** control into the middle table column and set the following properties:

   ID: MainZone

   HeaderText: Main

10. Save the file.

Your page now has two distinct zones that you can control separately. However, neither zone has any content, so creating content is the next step. For this walkthrough, you work with Web Parts controls that display only static content.

The layout of a Web Parts zone is specified by a <zonetemplate> element. Inside the zone template, you can add any ASP.NET control, whether it is a custom Web Parts control, a user control, or an existing server control. Notice that here you are using the Label control, and to that you are simply adding static text. When you place a regular server control in a **WebPartZone** zone, ASP.NET treats the control as a Web Parts control at run time, which enables Web Parts features on the control.

To create content for the main zone

1. In **Design** view, drag a **Label** control from the **Standard** tab of the Toolbox into the contents area of the zone whose **ID** property is set to MainZone.

2. Switch to **Source** view. Notice that a <zonetemplate> element was added to wrap the **Label** control in the MainZone.

3. Add an attribute named **title** to the <asp:label> element, and set its value to Content. Remove the Text="Label" attribute from the <asp:label> element. Between the opening and closing tags of the <asp:label> element, add some text such as **Welcome to my Home Page** within a pair of <h2> element tags. Your code should look as follows.

```
<asp:webpartzone id="MainZone" runat="server" headertext="Main">
    <zonetemplate>
        <asp:label id="Label1" runat="server" title="Content">
            <h2>Welcome to My Home Page</h2>
        </asp:label>
    </zonetemplate>
</asp:webpartzone>
```

4. Save the file.

Next, create a user control that can also be added to the page as a Web Parts control.

To create a user control

1. Add a new Web user control to your site to serve as a search control. Deselect the option to **Place source code in a separate file**. Add it in the same directory as the WebPartsDemo.aspx page, and name it SearchUserControl.ascx.

> **NOTE**
>
> The user control for this walkthrough does not implement actual search functionality; it is used only to demonstrate Web Parts features.

2. Switch to **Design** view. From the **Standard** tab of the Toolbox, drag a TextBox control onto the page.
3. Place the insertion point after the text box you just added, and press ENTER to add a new line.
4. Drag a Button control onto the page on the new line below the text box you just added.
5. Switch to **Source** view. Ensure that the source code for the user control looks like the following example.

```
<%@ control language="C#"
    classname="SearchUserControl" %>
<asp:textbox runat="server"
  id=" TextBox1"></asp:textbox>
<br />
<asp:button runat="server"
  id=" Button1" text="Search" />
```

6. Save and close the file.

Now you can add Web Parts controls to the Sidebar zone. You are adding two controls to the Sidebar zone, one containing a list of links and another that is the user control you created in the previous procedure. The links are added as a standard **Label** server control, similar to the way you created the static text for the Main zone. However, although the individual server controls contained in the user control could be contained directly in the zone (like the label control), in this case they are not. Instead, they are part of the user control you created in the previous procedure. This demonstrates a common way to package whatever controls and extra functionality you want in a user control, and then reference that control in a zone as a Web Parts control.

At run time, the Web Parts control set wraps both controls with GenericWebPart controls. When a **GenericWebPart** control wraps a Web server control, the generic part control is the parent control, and you can access the server control through the parent control's ChildControl property. This use of generic part controls enables standard Web server controls to have the same basic behavior and attributes as Web Parts controls that derive from the **WebPart** class.

To add Web Parts controls to the sidebar zone

1. Open the WebPartsDemo.aspx page.
2. Switch to **Design** view.
3. Drag the user control page you created, SearchUserControl.ascx, from **Solution Explorer** into the zone whose **ID** property is set to SidebarZone, and drop it there.
4. Save the WebPartsDemo.aspx page.
5. Switch to **Source** view.
6. Inside the <asp:webpartzone> element for the SidebarZone, just above the reference to your user control, add an <asp:label> element with contained links, as shown in the following example. Also, add a **Title** attribute to the user control tag, with a value of **Search**, as shown.

```
<asp:WebPartZone id="SidebarZone" runat="server"
                 headertext="Sidebar">
    <zonetemplate>
        <asp:label runat="server" id="linksPart" title="My Links">
            <a href="http://www.asp.net">ASP.NET site</a>
            <br />
            <a href="http://www.gotdotnet.com">GotDotNet</a>
            <br />
            <a href="http://www.contoso.com">Contoso.com</a>
            <br />
        </asp:label>
        <uc1:SearchUserControl id="searchPart"
          runat="server" title="Search" />
    </zonetemplate>
</asp:WebPartZone>
```

7. Save and close the file.

Now you can test your page by browsing to it in your browser. The page displays the two zones. The following screen shot shows the page.

Web Parts Demo page with two zones

Figure 3: Web Parts VS Walkthrough 1 Screenshot

In the title bar of each control is a downward arrow that provides access to a verbs menu of available actions you can perform on a control. Click the verbs menu for one of the controls, then click the **Minimize** verb and note that the control is minimized. From the verbs menu, click **Restore**, and the control returns to its normal size.

Enabling Users to Edit Pages and Change Layout

Web Parts provides the capability for users to change the layout of Web Parts controls by dragging them from one zone to another. In addition to allowing users to move **WebPart** controls from one zone to another, you can allow users to edit various characteristics of the controls, including their appearance, layout, and behavior. The Web Parts control set provides basic editing functionality for **WebPart** controls. Although you will not do so in this walkthrough, you can also create custom editor controls that allow users to edit the features of **WebPart** controls. As with changing the location of a **WebPart** control, editing a control's properties relies on ASP.NET personalization to save the changes that users make.

In this part of the walkthrough, you add the ability for users to edit the basic characteristics of any **WebPart** control on the page. To enable these features, you add another custom user control to the page, along with an <asp:editorzone> element and two editing controls.

To create a user control that enables changing page layout

1. In Visual Studio, on the **File** menu, select the **New** submenu, and click the **File** option.
2. In the **Add New Item** dialog, select **Web User Control**. Name the new file DisplayModeMenu.ascx. Deselect the option to **Place source code in separate file**.
3. Click Add to create the new control.
4. Switch to **Source** view.
5. Remove all the existing code in the new file, and paste in the following code. This user control code uses features of the Web Parts control set that enable a page to change its view or display mode, and also enables you to change the physical appearance and layout of the page while you are in certain display modes.

```
<%@ Control Language="C#" ClassName="DisplayModeMenuCS" %>

<script runat="server">

    // Use a field to reference the current WebPartManager control.
    WebPartManager _manager;
    void Page_Init(object sender, EventArgs e) {
        Page.InitComplete += new EventHandler(InitComplete);
    }
    void InitComplete(object sender, System.EventArgs e) {
        _manager = WebPartManager.GetCurrentWebPartManager(Page);
        String browseModeName = WebPartManager.BrowseDisplayMode.Name;
        // Fill the drop-down list with the names of supported display modes.
        foreach (WebPartDisplayMode mode in
        _manager.SupportedDisplayModes) {
            String modeName = mode.Name;
            // Make sure a mode is enabled before adding it.
            if (mode.IsEnabled(_manager)) {
                ListItem item = new ListItem(modeName, modeName);
                DisplayModeDropdown.Items.Add(item);
            }
        }
        // If Shared scope is allowed for this user, display the
        // scope-switching UI and select the appropriate radio
        // button for the current user scope.
        if (_manager.Personalization.CanEnterSharedScope) {
            Panel2.Visible = true;
            if (_manager.Personalization.Scope ==
            PersonalizationScope.User)
                RadioButton1.Checked = true;
            else
                RadioButton2.Checked = true;
        }
    }

    // Change the page to the selected display mode.
    void DisplayModeDropdown_SelectedIndexChanged(object sender,
        EventArgs e) {
        String selectedMode = DisplayModeDropdown.SelectedValue;
        WebPartDisplayMode mode =
            _manager.SupportedDisplayModes[selectedMode];
        if (mode != null)
            _manager.DisplayMode = mode;
    }
    // Set the selected item equal to the current display mode.
    void Page_PreRender(object sender, EventArgs e) {
        ListItemCollection items = DisplayModeDropdown.Items;
        int selectedIndex =
        items.IndexOf(items.FindByText(_manager.DisplayMode.Name));
        DisplayModeDropdown.SelectedIndex = selectedIndex;
    }
    // Reset all of a user's personalization data for the page.
```

```
    protected void LinkButton1_Click(object sender, EventArgs e) {
        _manager.Personalization.ResetPersonalizationState();
    }
    // If not in User personalization scope, toggle into it.
    protected void RadioButton1_CheckedChanged(object sender, EventArgs e) {
        if (_manager.Personalization.Scope == PersonalizationScope.Shared)
            _manager.Personalization.ToggleScope();
    }

    // If not in Shared scope, and if user has permission, toggle
    // the scope.
    protected void RadioButton2_CheckedChanged(object sender,
    EventArgs e) {
        if (_manager.Personalization.CanEnterSharedScope &&
            _manager.Personalization.Scope == PersonalizationScope.User)
            _manager.Personalization.ToggleScope();
    }
</script>

<div>
    <asp:Panel ID="Panel1" runat="server"
      BorderWidth="1" Width="230" BackColor="lightgray"
        Font-Names="Verdana, Arial, Sans Serif">
        <asp:Label ID="Label1" runat="server"
          Text=" Display Mode" Font-Bold="true"
            Font-Size="8" Width="120" />
        <asp:DropDownList ID="DisplayModeDropdown"
          runat="server" AutoPostBack="true" Width="120"
            OnSelectedIndexChanged="DisplayModeDropdown_SelectedIndexChanged" />
        <asp:LinkButton ID="LinkButton1" runat="server"
             Text="Reset User State"
             ToolTip="Reset the current user's personalization data for the page."
             Font-Size="8" OnClick="LinkButton1_Click" />
        <asp:Panel ID="Panel2" runat="server"
            GroupingText="Personalization Scope" Font-Bold="true"
            Font-Size="8" Visible="false">
            <asp:RadioButton ID="RadioButton1" runat="server"
                Text="User" AutoPostBack="true"
                GroupName="Scope"
                OnCheckedChanged="RadioButton1_CheckedChanged" />
            <asp:RadioButton ID="RadioButton2" runat="server"
                Text="Shared" AutoPostBack="true"
                GroupName="Scope"
                OnCheckedChanged="RadioButton2_CheckedChanged" />
        </asp:Panel>
    </asp:Panel>
</div>
```

6. Save the file by clicking the save icon on the toolbar, or by selecting **Save** on the **File** menu.

To enable users to change the layout

1. Open the WebPartsDemo.aspx page, and switch to **Design** view.

2. Position the insertion point in the **Design** view just after the **WebPartManager** control that you added earlier. Add a hard return after the text so that there is a blank line after the **WebPartManager** control. Place the insertion point on the blank line.

3. Drag the user control you just created (the file is named DisplayModeMenu.ascx) into the WebPartsDemo.aspx page and drop it on the blank line.

4. Drag an EditorZone control from the **WebParts** section of the Toolbox to the remaining open table cell in the WebPartsDemo.aspx page.

5. From the **WebParts** section of the Toolbox, drag an AppearanceEditorPart control and a LayoutEditorPart control into the **EditorZone** control.

6. Switch to **Source** view. The resulting code in the table cell should look similar to the following code.

```
<td valign="top">
    <asp:EditorZone ID="EditorZone1" runat="server">
        <ZoneTemplate>
            <asp:AppearanceEditorPart ID="AppearanceEditorPart1"
              runat="server" />
            <asp:LayoutEditorPart ID="LayoutEditorPart1"
              runat="server" />
        </ZoneTemplate>
    </asp:EditorZone>
</td>
```

7. Save the WebPartsDemo.aspx file. You have created a user control that allows you to change display modes and change page layout, and you have referenced the control on the primary Web page.

You can now test the capability to edit pages and change layout.

To test layout changes

1. Load the page in a browser.
2. Click the **Display Mode** drop-down menu, and select **Edit**. The zone titles are displayed.
3. Drag the **My Links** control by its title bar from the Sidebar zone to the bottom of the Main zone. Your page should look like the following screen shot.

Web Parts Demo page with My Links control moved

Figure 4: Web Parts VS Walkthrough 2 Screenshot

1. Click the **Display Mode** drop-down menu, and select **Browse**. The page is refreshed, the zone names disappear, and the **My Links** control remains where you positioned it.

2. To demonstrate that personalization is working, close the browser, and then load the page again. The changes you made are saved for future browser sessions.

3. From the **Display Mode** menu, select **Edit**.

   Each control on the page is now displayed with a downward arrow in its title bar, which contains the verbs drop-down menu.

4. Click the arrow to display the verbs menu on the **My Links** control. Click the **Edit** verb.

   The **EditorZone** control appears, displaying the EditorPart controls you added.

5. In the **Appearance** section of the edit control, change the **Title** to My Favorites, use the **Chrome Type** drop-down list to select **Title Only**, and then click **Apply**. The following screen shot shows the page in edit mode.

Web Parts Demo page in Edit mode

Figure 5: Web Parts VS Walkthrough 3 Screenshot

1. Click the **Display Mode** menu, and select **Browse** to return to browse mode.
2. The control now has an updated title and no border, as shown in the following screen shot.

Edited Web Parts Demo page

Figure 4: Web Parts VS Walkthrough 4 Screenshot

Adding Web Parts at Run Time

You can also allow users to add Web Parts controls to their page at run time. To do so, configure the page with a Web Parts catalog, which contains a list of Web Parts controls that you want to make available to users.

To allow users to add Web Parts at run time

1. Open the WebPartsDemo.aspx page, and switch to **Design** view.

2. From the **WebParts** tab of the Toolbox, drag a CatalogZone control into the right column of the table, beneath the **EditorZone** control.

Both controls can be in the same table cell because they will not be displayed at the same time.

3. In the Properties pane, assign the string **Add Web Parts** to the HeaderText property of the **CatalogZone** control.

4. From the **WebParts** section of the Toolbox, drag a DeclarativeCatalogPart control into the content area of the **CatalogZone** control.

5. Click the arrow in the upper right corner of the **DeclarativeCatalogPart** control to expose its Tasks menu, and then select **Edit Templates**.

6. From the **Standard** section of the Toolbox, drag a **FileUpload** control and a **Calendar** control into the **WebPartsTemplate** section of the **DeclarativeCatalogPart** control.

7. Switch to **Source** view. Inspect the source code of the <asp:catalogzone> element. Notice that the **DeclarativeCatalogPart** control contains a <webpartstemplate> element with the two enclosed server controls that you will be able to add to your page from the catalog.

8. Add a **Title** property to each of the controls you added to the catalog, using the string value shown for each title in the code example below. Even though the title is not a property you can normally set on these two server controls at design time, when a user adds these controls to a **WebPartZone** zone from the catalog at run time, they are each wrapped with a **GenericWebPart** control. This enables them to act as Web Parts controls, so they will be able to display titles.

   The code for the two controls contained in the **DeclarativeCatalogPart** control should look as follows.

```
<asp:DeclarativeCatalogPart ID="DeclarativeCatalogPart1" runat="server">
    <WebPartsTemplate>
        <asp:Calendar ID="Calendar1" runat="server" title="My Calendar" />
        <asp:FileUpload ID="FileUpload1" runat="server" title="Upload Files" />
    </WebPartsTemplate>
</asp:DeclarativeCatalogPart>
```

9. Save the page.

You can now test the catalog.

To test the Web Parts catalog

1. Load the page in a browser.

2. Click the **Display Mode** drop-down menu, and select **Catalog**.

   The catalog titled **Add Web Parts** is displayed.

3. Drag the **My Favorites** control from the Main zone back to the top of the Sidebar zone, and drop it there.

4. In the **Add Web Parts** catalog, select both check boxes, and then select **Main** from the drop-down list that contains the available zones.

5. Click **Add** in the catalog. The controls are added to the Main zone. If you want, you can add multiple instances of controls from the catalog to your page.

   The following screen shot shows the page with the file upload control and the calendar in the Main zone.

```
**Figure 5**: Controls added to Main zone from the catalog
```

6. Click the **Display Mode** drop-down menu, and select **Browse**. The catalog disappears and the page is refreshed.
7. Close the browser. Load the page again. The changes you made persist.

[How Do I:] Learn the Tips and Tricks of Experts?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

View tips and tricks including encrypting sensitive information stored in the web.config file, posting content to a different page, simplifying complex URLs using URL remapping, and much, much more.

Watch video (18 minutes)

[How Do I:] Create a Multi-Lingual Site with Localization?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Learn how to create culture-aware and locale-specific web content with no additional code. Use the Resource Editor to create page-level and application-level resources.

Watch video (13 minutes)

[How Do I:] Make use of Caching?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Watch a demonstration of Page Output Caching followed by an overview of the new Database Caching support for SQL Server 2000 and SQL Server 2005.

Watch video (11 minutes)

[How Do I:] Make Greater use of Caching?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Watch a demonstration of Partial-Page Output Caching, followed by an overview of the Cache API that demonstrates how to efficiently bind a data presentation control to an XML file.

Watch video (15 minutes)

[How Do I:] Utilize Web Parts and Personalization?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Learn how to use the new Web Parts and Personalization features to build customizable web pages whose content and layout can be modified by the user.

Watch video (13 minutes)

[How Do I:] Customize my Site with Profiles and Themes?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Learn how to use Profiles to collect per-user configuration information and apply Themes to extend a consistent look-and-feel throughout the Web site.

Watch video (12 minutes)

[How Do I:] Secure my Site using Membership and Roles?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Learn how to secure a web site using the new Membership and Roles features of ASP.NET 2.0. Topics include user registration, password recovery, and restricting access to content with roles.

Watch video (17 minutes)

[How Do I:] Create a "Contact Us" Page?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Build a web page to collect information from the user with the Wizard control, validate that information, and use the System.Net.Mail classes to send a confirmation email message.

Watch video (13 minutes)

[How Do I:] Create a Full-Featured Customer Login Portal?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Follow along through the creation of a fictitious customer portal to learn about master pages, themes, membership, roles, site navigation, user profiles, and the Web Site Administration Tool.

Watch video (27 minutes)

[How Do I:] Use Master Pages and Site Navigation?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Create a web site with a consistent layout and design across all its pages using ASP.NET 2.0 MasterPages. See how easy it is to add navigation to a web site using the new TreeView and SiteMapPath controls.

Watch video (13 minutes)

[How Do I:] Create Data-Driven Web Sites?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

See how simple it is to create data-driven web sites using ASP.NET 2.0, Visual Web Developer 2005 Express Edition, and SQL Server 2005 Express Edition. Learn how to create a database, add its data, and display that data on a web page.

Watch video (13 minutes)

[How Do I:] Implement an HttpModule?

2/20/2020 • 2 minutes to read • Edit Online

by Scott Golightly

In this video Scott Golightly shows how to implement a simple HttpModule that uses the BeginRequest and EndRequest events to store some data about the request and later display that data to the user. Scott also shows how to register the module in the Web.config file.

Watch video (13 minutes)

[How Do I:] Set Up the SQL Membership Provider

2/20/2020 • 2 minutes to read • Edit Online

by Patrick Hynds

Join Patrick Hynds as he demonstrates how to set up the SQL Membership Provider to add Forms authentication to your ASP.NET 2.0 Web site. There are a few tips and tricks involved, such as using the aspnet_regsql.exe utility, which are covered in the video.

Watch video (9 minutes)

[How Do I:] Implement URL Rewriting?

2/20/2020 • 2 minutes to read • Edit Online

by Scott Golightly

In this video Scott Golightly shows how to create an ASP.NET HttpModule to "rewrite" the URL when a request for a web page comes in. You may want to rewrite URLs to create friendly URLs or to direct an old URL to a new URL. We will look at the code needed to implement URL rewriting and also how to handle page post back events.

Watch video (22 minutes)

[How Do I:] Utilize the CSS Friendly Control Adapters?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

The CSS Friendly Control Adapters allow you to alter the HTML that is rendered by a standard ASP.NET 2.0 server control. In this video we learn that the standard ASP.NET Menu control renders an HTML `<table>` element, but with the CSS Friendly Control Adapters the same control will render an HTML `<ul>` list element, improving the menu's accessibility and presentation.

Watch video (26 minutes)

[How Do I:] Handle Application Events using an HttpModule?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

Learn how to create an HttpModule that handles application events during the processing of a page request. The sample module will write information to a log file at various points in the page lifecycle. We also see how the HttpModule is configured for use in a sample web site.

Watch video (19 minutes)

[How Do I:] Use Cascading Style Sheets for Web Page Layout?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video we learn how to use `<div>` elements in combination with cascading style sheets (CSS) to create robust and higher performance web pages. The `<div>` based approach will be compared to the `<table>` based layout approach used by most web sites over recent years. Then, several CSS-based approaches will be shown, ranging from absolute positioning to floating elements. We also learn the benefits of separating structural HTML from design with the use of CSS.

Watch video (29 minutes)

[How Do I:] Create a Custom Membership Provider?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

A Membership Provider allows a web application to store and retrieve membership data for a user, and the standard ASP.NET Membership Provider uses pre-defined SQL Server tables. In this video we learn how to create a custom membership provider that uses custom SQL Server tables separate from the pre-defined tables used by the standard provider. The principles covered in the video will apply to creating custom membership providers using other databases such as Access or Oracle. After learning to create the custom membership provider, we learn how to configure the provider in a web application, and see a demonstration of creating a new user and authenticating the new user with the custom membership provider.

Watch video (29 minutes)

[How Do I:] Create a Custom Profile Provider?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video we learn how to create a custom profile provider to store and retrieve data associated with a user profile in SQL Server tables separate from the standard ASP.NET membership provider's aspnet_Profile table. The principles covered in this video will apply to creating profile providers for other databases like Access and Oracle. After learning how to create the custom profile provider we learn how to install the provider in a web site and see a demonstration of loading and saving profile data.

Watch video (32 minutes)

[How Do I:] Implement Site Navigation in ASP.NET?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video we learn how to define a sitemap and use it with the Menu, TreeView, and Sitemap server controls. We see how to use a sitemap on a master page for site-wide menus and how we can have single or multiple sitemaps on a page. In addition, we are shown how to integrate a sitemap with ASP.NET roles by using "security trimming" to dynamically show or hide menu options for users with different access levels.

Watch video (29 minutes)

[How Do I:] Use Validation Controls in ASP.NET?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video learn how to use the validation controls available in ASP.NET to implement validation on your web pages. All the major validation controls such as RequiredFieldValidator and RegularExpressionValidator will be discussed. In addition, learn how to use the CustomValidator when one of the standard validators does not meet your need. Both server and client side validation options are shown. See how to do single validation on a UI control as well as multiple validations.

Watch video (31 minutes)

[How Do I:] Create a Custom User Control in ASP.NET?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will demonstrate how to create a custom user control in ASP.NET that can be used throughout a web site or across many web sites. Start out by learning the basics of creating a user control that will be used in multiple pages including validation, controlling formatting using style elements, and loading/saving data for the user interface elements. Throughout the video considerations for building user controls that can be easily maintained and used across multiple pages are discussed.

Watch video (27 minutes)

[How Do I:] Implement Health Monitoring for an ASP.NET Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to implement health monitoring to get detailed run-time information for an ASP.NET application. Learn the powerful and flexible configuration options for health monitoring including health monitoring events, aka web events, providers for storing data, rules for mapping events to providers, profiles for commonly used settings, and buffermode to optimize health monitoring for best performance. Then see a sample web application in action with health monitoring enabled writing events to the Windows event log.

Watch video (21 minutes)

[How Do I:] Implement Tracing in an ASP.NET Web Site?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show you how to implement tracing in an ASP.NET web site to monitor or measure the performance and to diagnose errors. Learn how to add tracing to an entire web site as well as individual pages. See how to add custom trace messages in pages and business objects to aid in assessing site performance and in diagnosing errors. Learn the differences between tracing in an ASP.NET page and in using System.Diagnostics.Trace for tracing information in business objects. Writing trace information to log files and viewing trace information in the trace viewer are also discussed.

Watch video (30 minutes)

[How Do I:] Event Handlers in ASP.NET Web Pages and Controls

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create event handlers for ASP.NET web pages and web server controls. First, learn how to create page level events for the standard page events provided by the .NET Framework. See how to automatically bind the events to a page using the AutoEventWireup attribute as well as programmatically bind the events. Next, learn how to create and bind event handlers for the standard web server control events. Also learn how to connect multiple events for different controls to the same event handler. Finally, see the usage of the AutoPostbackTrue property for web server controls.

Watch video (32 minutes)

[How Do I:] Implement a Custom Health Monitoring Event

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create a custom health monitoring event that extends a standard health monitoring events in ASP.NET. The custom provides additional event information and formats it for a health monitoring event provider. A custom HTTP module is then created to raise the custom health monitoring event explicitly since the .NET Framework only raises the standard health monitoring events. In addition, the custom health monitoring event is raised explicitly in the page behind code for an .aspx page.

Watch video (26 minutes)

[How Do I:] Use Control State to Persist Information for a Custom Web Server Control

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to store information related to a custom web server control in the control state which is independent of the ViewState information for the control. Unlike ViewState the control state can not be turned off and is therefore a more reliable way to store important information for a control. A discussion of what types of information are appropriate to store in control state is also included.

Watch video (13 minutes)

Read, Write, and Delete Cookies in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to read, write, and delete cookies in an ASP.NET application. First, learn the basic operations for manipulating cookies. Then learn approaches to storing multiple values in a single cookie using name-value pairs called subkeys. Next, learn how to limit the scope of cookies to a particular application domain or folder. See how to modify values and expiration dates in existing cookies and how to delete an existing cookie. In addition, several considerations for using cookies are also discussed.

Watch video (25 minutes)

[How Do I:] Save and Load View State Information for a Custom Web Server Control

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to persist and restore information in the ViewState of a custom user control. First, learn how to persist simple values containing .NET primitive types such as String, Int32, Boolean, etc. Then see how to persist complex types such as Class which contain properties storing information. The sequence of processing View State information during the lifecycle of an ASP.NET page is also discussed.

Watch video (28 minutes)

[How Do I:] Create and Use Application Level Events in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create an Application Class File (Global.asax) that contains application level event handlers such as Application_Start and Application_BeginRequest. Then the sequence of application level events in the application lifecycle will be discussed as a basis for determining where certain types of operations would be best performed during the application lifecycle.

Watch video (12 minutes)

[How Do I:] Simple File Uploads in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video I will demonstrate, using ASP.NET, uploading a single file from the client machine to your server. This will be the first in a series of uploading files videos.

Watch video (17 minutes)

[How Do I:] Multiple File Uploads in ASP.NET 2

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video I will demonstrate uploading a dynamically determined number of files to your ASP.NET application.

Watch video (16 minutes)

[How Do I:] Multiple File Uploads in ASP.NET 1

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video I will elaborate on uploading multiple files to an ASP.NET application.

Watch video (15 minutes)

[How Do I:] File Uploads with an AJAX Style Interface

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video I will demonstrate, using ASP.NET, an AJAX style of uploading files from the client machine to your server. I say AJAX style because there is actually a problem using AJAX to upload files. The video will demonstrate what I mean.

Watch video (27 minutes)

[How Do I:] Work with Master Pages Declaratively and Programmatically

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show several aspects of defining and using master pages in an ASP.NET web site. First, see how to create master pages declaratively using the ASP.NET master page model and learn what information is best suited to a master page compared to an individual content page. Next, see how to programmatically assign master pages on-the-fly in an individual content page. Also learn how to create a base page class which assigns a master page programmatically for all pages that inherit from the base class. In addition, see how to set the master page in the web.config file. Lastly, see how to access elements in a master page from an individual content page including some best practices for structuring access to master page elements.

Watch video (29 minutes)

[How Do I:] Handle Events in Master and Content Pages

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how events are handled in master and individual content pages. Even though the end result of a master and individual content page is a single ASP.NET page rendered in the user's browser the event handling in each type of page is handled separately. If a control is located in the master page the corresponding event handler is located in the master page by default. The same is true for controls in the content page. See two approaches to having the events for a control located in the master page handled in the code behind of the content page. This allows "communication" between the master page and content page.

Watch video (23 minutes)

[How Do I:] Use the ObjectDataSource with a Data Access Class and Business Object

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use the ObjectDataSource as the intermediate layer between data bound user interface elements and a custom data access class for a business object. Uses of the ObjectDataSource in the GUI Design mode and declaratively in the source view of an .aspx page are discussed. In addition, the considerations for design of the data access class and business object for use with the ObjectDataSource are covered.

Watch video (32 minutes)

[How Do I:] Create User Selectable Themes for a Web Site

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create multiple themes for a web site and then allow the user to select which theme is applied to the site. See how to create a simple user interface that allows the user to select each of the themes with a user control. In addition, learn how to set a theme for a content page from a user control on a master page.

Watch video (19 minutes)

[How Do I:] Share Data Between Client JavaScript and Server Code Using a Hidden Field

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to share data in between JavaScript and server-side code by using a hidden field in an ASP.NET page. Next, learn how to use the RegisterHiddenField method in server-side code to programmatically create a hidden field on the client. In addition, see how to programmatically create a HiddenField server control for sharing data on an ASP.NET page. Finally, use the RegisterArrayDeclaration method to create a container in server code for storing multiple values that is rendered to the page where it can be accessed by JavaScript.

Watch video (21 minutes)

[How Do I:] Add JavaScript to An ASP.NET Page

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to include JavaScript to an ASP.NET page for use on the client page to provide a richer and more robust user experience. First, see how to include JavaScript directly within an ASP.NET page and reference the script from within HTML page elements. Next, see how to abstract the JavaScript to an external JavaScript file which offers the advantage of being cached by the browser and can be used by multiple pages. Lastly, learn how to add JavaScript to a page dynamically at runtime which has the advantage of including script for a specific situation or where information such as a control ID is not known until runtime. As part of the dynamic script sample see how to add JavaScript that can be automatically executed when the page loads as well as the click event for button controls (Button, LinkButton, and ImageButton).

Watch video (24 minutes)

[How Do I:] Add JavaScript Event Handlers to ASP.NET Server Controls

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to interface JavaScript methods with ASP.NET server controls to provide client side functionality for the server controls. First, see how to add client event handlers declaratively by extending ASP.NET server controls with custom attributes. Next, see how to add attributes for mapping client methods to ASP.NET server controls programmatically which offers the advantage of being done at runtime. Finally, learn how to reference the ID of a server control, which is rendered dynamically by ASP.NET, in JavaScript code.

Watch video (18 minutes)

[How Do I:] Create and Call a Simple Web Service in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create a web service in ASP.NET and then call the service from another ASP.NET web site. First, learn how to create an .asmx component which represents a web service in an ASP.NET web site. When creating the web service learn how to control several aspects of the web service functionality with web service attributes. Next, see how to test the web service in the Visual Studio web service test page. Then learn how ASP.NET allows many .NET data types to be returned from a web service. Create a business class library project and then use a class in that project as a return value from a web service by serializing the custom business object instance. Finally, see how to consume a web service from an ASP.NET web site.

Watch video (33 minutes)

[How Do I:] Deploy a Web Site Using the Copy Web Site Tool

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to deploy a web site using the Copy Web Site Tool in Visual Studio. First see how to connect to a remote web site and deploy an entire site to the target location. Next, learn how to synchronize an entire source and target web site. In addition, see how to copy and synchronize individual or groups of files including how the Copy Web Site tool provides status indicators of differences between files. As part of this process see how the tool provides options on a file-by-file basis for decision making when there are differences in status between two or more files.

Watch video (17 minutes)

[How Do I:] Create and Use a Custom Configuration Section in an ASP.NET Configuration File

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to extend the standard set of ASP.NET configuration settings with your own XML configuration elements. First, see how to create a configuration section handler which is required to interpret and process the information in custom XML configuration elements. During this learn how to use declarative model for defining the behavior of a configuration section handler. Next, see how to add a custom section handler and custom elements to an ASP.NET configuration file. Finally, see how to programmatically access the custom configuration data.

Watch video (19 minutes)

[How Do I:] Configure an ASP.NET Web Site for a .NET Framework Version

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to configure an ASP.NET web site to use a specific version of ASP.NET/.NET Framework. First see how to identify what version of the .NET Framework a web site is associated with by viewing the script map in Internet Information Server (IIS). See how a script map is associated with the root in IIS and then with individual web sites. Next learn about the ASP.NET IIS Registration tool (aspnet_regiis.exe) used to configure IIS or an ASP.NET web site to use a specific version of the .NET Framework. Using this information see how a single web site is configured to use a different version of the .NET Framework than is the default to IIS. Finally, see two different web sites under the same IIS where one is running under .NET Framework 2.0 and the other under 1.1.

Watch video (12 minutes)

How Do I Use the ASP.NET IIS Registration Tool to Configure ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the ASP.NET IIS Registration Tool to configure ASP.NET. First, see how file extensions are mapped to ASP.NET in the IIS Manager on a global and web-site-by-web site basis. These script maps provide the basis for configuring individual ASP.NET applications to run under a specific version of the .NET Framework. Next, see how aspnet_regiis.exe, the IIS Registration Tool command line utility, is specific to each version of the .NET Framework and how it can be used for a variety of tasks like determining what versions of ASP.NET are installed on a computer and what ASP.NET applications are mapped to that version. Then, learn how install and uninstall ASP.NET on a computer using the registration tool. Also learn how to use the registration tool to install, uninstall, or update multiple ASP.NET applications for a specific version of the .NET Framework. For example, see how to install ASP.NET 2.0 and update script ma

Watch video (27 minutes)

[How Do I:] Extend and Customize an ASP.NET Server Control for a Specific Purpose

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to extend a standard ASP.NET server control and customize it for a specific purpose. Specialized controls provide an convenient way to implement standardized user interface elements for multiple web sites for individuals or teams of developers. In this example, see how to extend the DropDownList control to create a special purpose year selection control. Learn how to add properties for custom attributes that control the behavior of the range of years that can be displayed. Next, see how those custom attributes can be set in declarative syntax like standard attributes of a control. See how several additional properties can then be added to provide additional functionality for controlling the list behavior. Finally, see how an extended ASP.NET server control can be moved to a separate assembly so that it can be used across multiple web sites.

Watch video (26 minutes)

[How Do I:] Use the Ability to Create Groups with the ListView Control for Different Data

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to group items when displaying data in a ListView control. First, see the basics of item layout in the ListView control with the LayoutTemplate and the ItemTemplate. Then, learn how the GroupTemplate relates to the LayoutTemplate and ItemTemplate within a ListView to establish a group of data. See how to use floating DIV elements to create a flexible tabular layout since any of the templates used with the ListView can contain any HTML. This provides significant flexibility in creating groupings of data using the ListView control. Finally, see some options for enhancing the look by manipulating the CSS styles used in the ListView templates and how to use the GroupSeparatorTemplate as well as the EmptyItemTemplate.

Watch video (23 minutes)

[How Do I:] Make HTML elements accessible from server side code

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to make standard HTML elements in an .aspx page accessible from server side code so they can be used in page processing like a standard ASP.NET server control. First, see how the addition of a runat="server" attribute to a standard HTML control like a allows it to be referenced in server side code with full Intellisense. Next, see several examples of how you might manipulate HTML elements on a page with this technique. Lastly, see how this technique can be used in conjunction with the new ListView control in .NET Framework Version 3.5 to control the layout of a list.

Watch video (21 minutes)

[How Do I:] Use Roles to Segment Functionality in an ASP.NET Web Site

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to maximize the use of roles in an ASP.NET web site after setting up ASP.NET Membership. First, learn how to setup roles using the built-in role manager in Visual Studio .NET. See how to define roles based upon the business needs associated with the web site. Once the roles are setup learn how to structure your web site from a folder and page hierarchy perspective to most efficiently accommodate the roles and business needs. As part of this see how to use the roles attribute in defining authorization in the web.config file associated with each folder. Also, see how to use the <location> element to apply authorization settings to a specific location such as a page.

Watch video (32 minutes)

[How Do I:] Work with Nested Master Pages to Create Standard Content Layouts

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use nested master pages to create individual master pages that represent different standard content layouts for a web site. First, see how several major commercial web sites use a standard set of content layouts. Next, see how to nest a master page within another master page, and use the design time support in Visual Studio 2008. Then, learn the considerations for establishing a "page architecture" which represents the major types of content layout used in a sample web site. Once that definition is complete see how to structure the nested master pages so developers can then select a master page, resulting in a standardized and consistent display of content for a web site.

Watch video (30 minutes)

[How Do I:] Detect Browser Capabilities in ASP.NET Web Pages

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to determine what capabilities a user's browser has when viewing pages in an ASP.NET web site. First, learn how to access an instance of the HttpBrowserCapabilities object from the ASP.NET Request object associated with the web page request. Next, see the different information available in the HttpBrowserCapabilities object such as the type of browser and whether the user's browser supports JavaScript and Cookies. Then see an example of how to user this information about the user's browser and determine if a crawler is accessing the web site so it can be redirected to a crawler specific web page.

Watch video (14 minutes)

[How Do I:] Map an ASP.NET Server Control to the Adaptor Used to Render It

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use a control adaptor to provide different renderings for an ASP.NET server control without actually changing the control itself. In this video, an ASP.NET BulletList control will be adapted to display each list item horizontally using DIV elements instead of the traditional UL elements. First, see how to create a class that inherits WebControlAdaptor and then implements the code to render the new list format. Next, learn how to map the new control adaptor to the ASP.NET server control in the .browser definition file. Then see how to use the new control adaptor on pages in a web site. Finally, learn how a control adaptor can be associated with either all browsers or specific types of browsers.

Watch video (23 minutes)

[How Do I:] Pass Information From One Page to Another Using a Query String

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how information can be passed from one page to another using a query string. First, see how to construct a query string including variable names and values from information on a data entry form. Next, see how to access the query string information when the page is posted including how multiple query string variables are handled. As part of the server side processing of query string information, see how to implement validation for existence of query string variables and if they contain the expected type of data. Finally, learn how to pass special characters including a space and an ampersand in a query string by encoding the string.

Watch video (25 minutes)

[How Do I:] Use the aspnet_merge.exe Utility to Merge Assemblies

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use the aspnet_merge.exe utility to combine assemblies that have been compiled using the aspnet_compiler.exe utility. First, view the output of the ASP.NET compilation process to learn what assemblies are created. Next, learn the mechanics of using the aspnet_merge.exe utility to merge assemblies from the compilation of a web site, first seeing how to control the compiled assembly names with the –prefix option. Then see how to merge all the assemblies for a compiled web site into a single assembly. Lastly, learn how to merge just the assemblies related to the content (aspx, ascs, etc.) into a single assembly, leaving the top level assemblies such as app_code.dll representing the /App_Code folder. During each option the advantages and disadvantages of that option are discussed.

Watch video (28 minutes)

[How Do I:] Implement a Cross Page PostBack in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create a Cross Page PostBack in ASP.NET, where a control on a source page raises a PostBack event to a different target page. First, learn how to configure a Button control to PostBack to a different target page. Then, learn how to get information from controls on the source page with the PreviousPage property and the FindControl method. Then, learn how to use public properties on the source page to expose data to the target page, and learn how to use the @PreviousPageType directive on the target page to access these properties. Finally, learn the difference between a Cross Page PostBack and the Server.Transfer method.

Watch video (29 minutes)

[How Do I:] Add Controls to an ASP.NET Web Page Programmatically

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to create an ASP.NET server control programmatically at runtime and add it to a page. First, learn the basic concept of adding a control to a page programmatically. Then, the concept of a "container" control is examined which is necessary for adding a new control programmatically at runtime. Next, learn considerations for nesting programmatically added controls, and how creating separate methods can compartmentalize the process to make it more maintainable. In addition, learn considerations for managing view state when adding controls dynamically.

Watch video (33 minutes)

[How Do I:] Use a Hidden Field to Store and Manipulate Client-Side Information

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use a hidden field as one approach to simple state management on an ASP.NET page and for communicating client side processing information. First, see how to add a hidden field to a page using an ASP.NET HiddenField server control and retrieve the value of the hidden field in server-side code after a post-back. Next, learn how to manipulate the value of the hidden field in client-side script, and then retrieve the modified value in server-side code. Finally, see an example of how to use several hidden fields to store information from client-side processing that can be posted back for server processing.

Watch video (24 minutes)

[How Do I:] Use the Fixednames Option with the Compiler Utility for Maximum Flexibility

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to use the fixednames option with the aspnet_compiler.exe utility to produce a consistent file names in compilation output. First, see how the compilation output of the aspnet_compiler.exe utility generates output files for an ASP.NET web site that represent the different components including pages, themes, and the folders in the site. See how the components are named and what they contain in relation to the original web site. Then, see how to use the fixednames option to standardize the output file names based upon the source files upon which they are based. Next, learn about considerations for using each of the compilation options when deploying updates to compiled web site, focusing on which components are most likely to be updated.

Watch video (23 minutes)

[How Do I:] Implement Command Buttons for Individual Items

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will show how to handle events associated with a button control in each item of a data-bound control like a ListView control. First, see how these data-bound controls have standard button event handlers for standard operations like Edit or Delete. Next, learn how to add a button which performs a custom action and how to handle events for this custom button action. Finally, see how to pass data to the custom event handler for identification of the item where the button click originated.

Watch video (34 minutes)

[How Do I:] Use Skins with CSS for a Flexible and Maintainable ASP.NET Web Site

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create skins for ASP.NET server controls and then incorporate CSS styles to control the appearance of the skinned controls. First, learn how to create a skin for an ASP.NET server control such as a Label that controls the appearance of labels throughout a web site. Next, see how to abstract the definition of the visual appearance for a skin to CSS styles. During this process learn the advantages of having the styling information for a skin in the CSS styles. Then see how to create multiple skins and corresponding styles for a single ASP.NET control such as a Label that can be used to standardize the appearance of certain types of labels throughout a web site. Finally, learn the advantages of applying a CSS style to multiple skins and the ability to apply it to a generic HTML element.

Watch video (29 minutes)

[How Do I:] Determine Whether to Use a Web Site or a Web Application Project

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels will contrast the differences between an ASP.NET web site project and a web application project. Learn the considerations for using one type of project or the other. First, learn about the major attributes of a web application project including its folder basis. Next, see the major attributes of a web site project and its traditional Visual Studio project based nature which provides more granularity and flexibility including adding classes, dealing with namespaces, and referencing user controls or pages programmatically. The compilation model for each type of web site is then discussed along with alternatives that include the use of the aspnet_compiler.exe and aspnet_merge.exe utilities and the Visual Studio 2008 web deployment project.

Watch video (29 minutes)

[How Do I:] Write Web Events to a SQL Server Database Using the SqlWebEventProvider

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the ASP.NET health monitoring SqlWebEventProvider to log errors in a web site to a SQL Server database. First, learn the role of the provider and events in ASP.NET health monitoring. Next, see how to configure a SQL Server database with the necessary objects for recording health monitoring events using the aspnet_regiis utility, the same utility used to configure ASP.NET Membership. Then, learn how to configure health monitoring in the web.config file to record events in an ASP.NET web site to the newly created SQL Server database. As part of this configuration, see how the root web.config file in the .NET Framework 2.0 has both providers and events defined that can be leveraged when configuring your health monitoring. These fundamentals are a base upon which custom events can be created that log your own specific information to a SQL Server database in an ASP.NET web site.

Watch video (31 minutes)

[How Do I:] Use ASP.NET to Send Email from a Web Site

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create and send an email in an ASP.NET web site. First, learn about the core classes in the System.Net.Mail namespace for sending mail in an ASP.NET web site. See how to create an email message using the MailMessage class including how to use the MailAddress class for the From address and how to include one or more To addresses. Next, see how email is sent using the SmtpClient class. Finally, learn about the additional options for configuring the email message such as CC, BCC, Priority, and adding attachments.

Watch video (25 minutes)

[How Do I:] Configure Email Notification for Health Monitoring on an ASP.NET Web Site

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to configure email notification for health monitoring in an ASP.NET web site. First, see how to configure the sending of email in an ASP.NET web site through the use of the <emailSettings> element in the web.config file. Next, learn how to add the SimpleMailWebEventProvider which sends emails for health monitoring events as a provider. Then see the standard health monitoring events that can be used with email notification by examining the machine level health monitoring configuration. After reviewing the available events see a rule implemented that maps the "All Events" to the email provider. Upon starting the web site several emails are then sent and examined when they are received in Outlook. Finally, some basic principles of which events might be mapped to the health monitoring email provider are discussed.

Watch video (25 minutes)

[How Do I:] Use a Visual Studio 2008 Web Deployment Project

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the Visual Studio 2008 Web Deployment add-on to create deployment projects with a finer degree of control over how a web site is compiled and deployed. First, learn where to download and install the Web Deployment Project add-on for Visual Studio 2008. Then, create a web site project and an associated web deployment project. Learn the available configuration options for a web deployment project. See a brief review of the aspnet_compiler and aspnet_merge command line utilities which are integral to the web deployment project. Next, learn how to create multiple configurations for a web deployment project, e.g., one for Debug and one for Release modes. Then create a web application project and a corresponding web deployment project. Finally, see how the options and process for the web application project are the same as those for the web site project.

Watch video (26 minutes)

[How Do I:] Send Templated Emails for Health Monitoring Events in ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the TemplatedEmailWebEventProvider to send emails when health monitoring events occur that utilize a template for the email content. First, see how to configure the <provider> and <rules> elements in the web.config file to implement the use of templated email and associate a health monitoring event with the templated email provider. Once the templated provider is configured see how to create the email template using as standard .aspx page. Learn what information is available in the MailEventNotificaitonInfo class that is passed by the TemplatedEmailWebEventProvider to the template .aspx page. See how it can be used to include whatever information is appropriate in the email content. Finally, view the test web site which sends emails in response to health monitoring events. Then view the actual emails received that contain the health monitoring event information based upon the template.

Watch video (25 minutes)

[How Do I:] Send Email Asynchronously with ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video, Chris Pels shows how to use the System.Net.Mail classes in ASP.NET to send an asynchronous email message. First, see how to configure a web site to send email using the <mailSettings> element in the web.config file. Next, create a simple user interface for entering email information. Then learn how to create use the MailMessage class to create an email message in the code behind for the page. As part of that process create an event handler for the asynchronous callback following the sending of the email. In the event handler see how to use the instance of the AsynchCompletedEventArgs class which provides information about the email sending process. Finally, send a test email asynchronously, following the steps in the debug mode, and view the actual email received from the process.

[How Do I:] Embed an Image in an Email with ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

Chris Pels shows how to embed an image in an email with ASP.NET. He creates a web form (with fields for To, From, Subject, and Body), uses the AlternateView class to create text and HTML versions of an email, stores an image in a LinkedResource class instance, embeds it in the HTML AlternateView. He then adds both versions to the MailMessage object and sends the email twice, first with HTML-receiving capabilities enabled and then as text-only. Both email messages appear in Outlook. The HTML version shows the embedded image; the text version does not.

[How Do I:] Implement Error Handling when Sending Email with ASP.NET

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

Chris Pels shows how to implement error handling when sending an email with ASP.NET. He creates an ASP.NET web page to send email, shows how to configure <mailSettings> in the web.config file, describes the System.Net.Mail class and how it's used to create and send email messages. He then adds error handling using System.Net.Mail exception classes, which provide information about errors that can occur when sending email, and reviews the SmtpStatusCode enumeration, which provides a list of possible outcomes when sending an email with the SmtpClient. Finally, he sends a test email that raises an exception and reviews the error handling information in the Visual Studio debugger.

[How Do I:] Create a Custom Provider for Logging Health Monitoring Events

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

Chris Pels shows how to create a custom provider for the ASP.NET heath monitoring system, which records health monitoring events to a text-based log file. Learn how to create the custom provider class, which inherits from the BufferedWebEventProvider class, understand the methods and properties used to create the provider, and create a web site that uses it to write log files.

Watch video (26 minutes)

[How Do I:] Create a Reusable Component for Sending Email to a Distribution List

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create a component that can be used on multiple web pages and web sites that sends emails to a list of recipients. First, the ASP.NET web site will be configured to send email using the <mailSettings> in the web.config file. Then a class and several methods are created to read a list of recipients from a data source (DB, XML, etc.) and send an email message to each of the recipients using the System.Net.Mail classes. As part of this process exception handling is included. In addition, a user interface is created to allow the user to specify items such as the From address, Subject, add an attachment, etc.

[How Do I:] Use the FtpWebRequest Class to Create an FTP Connection to a FTP Server

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the FtpWebRequest class to create an FTP connection and transfer a file. First, create a simple .aspx form to select a file to transfer to the FTP server. Next, see the essential methods and properties of the FtpWebRequest class that need to be configured in order to establish an FTP connection. Then, see how to get the local file contents so the file can be transferred using a StreamReader and a StreamWriter to write it to the FtpWebRequest. Finally, a FtpWebResponse is obtained to determine the outcome of the transfer. This approach can be used to programmatically transfer files for a web application.

[How Do I:] Export Data to a Comma Delimited (CSV) File for an Application Like Excel

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to take data from a database or other source and export it to a comma delimited file that can be used in an application like Excel. First, a set of data is created as a DataTable object. Next, the Response for the current web page request is cleared and the header and content type are configured to be a csv file. Then the actual data is added to the response stream by first writing the column headers for the csv file followed by the data values. This approach can be useful when users require an export of data so it can be manipulated locally in a program like Excel.

Watch video (19 minutes)

[How Do I:] Use the Reponse.Filter Property to Replace HTML in an ASP.NET Page

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the Reponse.Filter property to intercept and alter the HTML being sent to a page. First, a sample page is created with some simple text. Then, a custom Stream class is created which serves as the replacement stream for the current stream being sent to the user's browser. In that custom stream class the contents of the page are retrieved from the stream, altered, and then written out to the response stream. In this custom Stream class the Write method is customized to replace the HTML in the base Response stream, thereby altering what is sent to the user's browser. Finally, the new stream class is assigned to the Response.Filter property in the Page_Load event, thereby, providing the mechanism for altering the page content.

[How Do I:] Use OutputCache to Cache an ASP.NET Page

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to utilize the built-in caching of ASP.NET to store a page in the cache so it does not have to be re-rendered. First, the simplest form of page caching is demonstrated where the entire page is cached for a specified period of time. Next, a more granular approach is taken where the values of QueryString variables are used as the basis for caching pages. Finally, see how to have the type of browser be the basis for caching a page.

Watch video (14 minutes)

[How Do I:] Cache Portions of an ASP.NET Page

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to cache one or more portions of an ASP.NET page by implementing the OutputCache for user controls on the page. First, an ASP.NET page is created and cached using the OutputCache directive. Several user controls are then created and cached for different durations. The relationship between page cached duration and control cache duration is reviewed. The different criteria for caching controls are reviewed including an example of VaryByControl where nested user controls can control caching of their parent controls.

Watch video (19 minutes)

[How Do I:] Control the Caching of an ASP.NET Page Based Upon Custom Information

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to control the criteria for caching an ASP.NET page based upon custom information. A sample page is created and then the OutputCache directive is used with the VaryByCustom attribute which contains a custom value. Next, the GetVaryCustomByString() method is overridden in the global.asax module which provides the handling of the custom attribute. In that method a string is returned that uniquely identifies the cached version of the page. Finally, there is a discussion about how caching using a custom value can be used in several ways for a web site.

Watch video (12 minutes)

[How Do I:] Cache an ASP.NET Page Based Upon Information in the HTTP Header

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to keep a page in the ASP.NET output cache based upon information in the page's HTTP header. First, the potential HTTP header values are reviewed. Then, a sample page is created and then the OutputCache directive is used with the VaryByHeader attribute which contains a value "accept-language", an HTTP header, to control caching based upon the language of the user's browser. The sample page is viewed in IE which is set to English and then in FireFox which is set to use French. Finally, the option to move the cache definition to a CacheProfile in the web.config file is discussed.

Watch video (12 minutes)

[How Do I]: Synchronize Data in Secondary User Control(s) Based Upon User Selections

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create two DropDownList controls where selecting an item in the first list populates the items in the second list. First, an ASP.NET page is created with two DropDownList controls, one for customer and the other for states in which the customer does business. The customer list is then populated in the code behind. Next, in the SelectedIndexChanged event of the customer list the items in the state list are populated based upon the selection. Finally, there is a discussion of how this approach can be applied to other types of controls and data.

Watch video (22 minutes)

[How Do I]: Use the ASP.NET Cache Object to Cache Application Information

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the ASP.NET Cache object to store application information. A sample page is created with a simple user interface and code is added that populates the grid with data from an XML disk file. Then the code is revised to cache the data in the application Cache object after it is initially retrieved and read from the cache for subsequent requests. Finally, methods are added to make use of absolute and sliding time based dependency for the cached object.

Watch video (22 minutes)

[How Do I]: Persist the State of a User Control During a Postback

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to persist the state of one or more objects in a user control. First, a user control is created that represents the ability for a user to specify filter criteria for a search. In addition, a companion Filter class is created to store the filter information. Several user interface elements are added to the filter control along with some methods and properties to store the current filter information in the Filter class instance. Next, the user control persistence is implemented using the RegisterRequiresControlState method and associated Save/Restore methods. These methods store the instance of the filter class and its data during page postbacks. Finally, there is a discussion of how to store multiple objects in control state implementation.

How Do I: Add Client Script Event Handlers Controls on an ASP.NET Page?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to add client script events to controls on an ASP.NET page. First, several ASP.NET controls are added to the page and an event handler is added for standard server-side processing of the Click event for a button. Next, client side JavaScript event handlers are added for Mouseover and Mouseout client side events that call JavaScript functions on the page to change a button background color. Next, key presses are captured for a textbox by adding a client side event handler. Then the OnClientClick attribute is shown as the way to handle client site click events for a button in addition to server side processing. Finally, several client side event handlers are defined by adding them programmatically in the server Page_Load event.

How Do I: Create and Use Classes in JavaScript?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create classes in JavaScript with functionality similar to other programming languages with object oriented capabilities. First a sample web site project is created with an external JavaScript file. A function() is created and the difference between using the function as a "function" and as a class constructor with the "new" keyword is discussed. Then public properties are added to the class constructor as well as private variables. Next a separate function is created and assigned as a method to the class. Alternatively, the same method is shown as a function defined in the class constructor. Finally, a private class method is created and used within the class constructor.

Watch video (18 minutes)

How Do I: Create an Efficient and Standardized Approach for Implementing CSS Styles?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to organize and implement CSS styles that provide a standardized look and feel to a web site. In addition, the styles are organized to provide maximum flexibility and reusability. A set of styles is created that focuses on the visual appearance of the site. First, a sample web site is created with a CSS file for a sample page. The first groups of styles created are oriented towards providing containers for content throughout the site. Next, a set of styles are added that focus on displaying the "state" of user interface elements. Finally, a set of styles for user interaction cues are created. Each of the styles is used with HTML elements on the sample page. There is also a discussion about using the same implementation approach for styles that control element layout on the site.

How to work with SQL Server Express to add database capabilities to your ASP.NET applications.

- What is a Database
- Understanding Database Tables and Records
- More about Column Data Types and Other Properties
- Designing Relational Database Tables
- Manipulating Database Data
- More Structured Query Language
- Understanding Security and Network Connectivity
- Connecting your Web Application to SQL Server 2005 Express Edition
- Using SQL Server Management Studio
- Getting Started with Reporting Services
- Building and Customizing Reports in Business Intelligence Development Studio
- Creating and Using Stored Procedures
- Enabling Full-Text Search in your Text Data

What is a Database?

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

This introduction covers the questions and terminology SQL Server beginners need to create and manage databases, such as: What is a SQL Server database? How is a SQL Server database different from an Excel spreadsheet? What do SQL Server databases do in my website or software applications? What's SQL Server Express' relation to Visual Studio Express? What do terms like "ADO.NET" mean?

Watch video (28 minutes)

NEXT

Understanding Database Tables and Records

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

SQL Server beginners will learn about tables and definitions of data types, properties, keys, etc. in this second video. Find out how table rows, columns, and fields interrelate and whether columns can be empty.

Watch video (24 minutes)

PREVIOUS NEXT

More about Column Data Types and Other Properties

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

SQL Server beginners will explore data integrity, learn which data types to use for what, and avoid common data type pitfalls.

Measuring the Business Value of AJAX

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

ASP.NET AJAX is well known for its ability to improve the user experience of Web applications. With Visual Studio Team System you can also measure the business value of adding ASP.NET AJAX to your Web applications. Specifically you can use the Load and Web Testing capabilities of Visual Studio Team System to explore how the difference in HTTP data transmission size affects the performance and scalability characteristics of the Web application.

Watch video (10 minutes)

PREVIOUS NEXT

Code Coverage of Automated Tests

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

This video demonstrates how to use code coverage as a metric for determining how effective our testing is of an ASP.NET Web application. After a test has completed, Visual Studio Team System reports on the percentage of code that was executed and indicates executed code with a green background and unexecuted code with a red background, making it easy to see the code that was covered by the test. You will also learn how you can use C# or Visual Basic to extend the automated test.

Watch video (6 minutes)

PREVIOUS NEXT

Custom Extraction Rules and Coded Web Tests

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

Visual Studio Team System makes it easy to test a Web application by recording a user's interaction with the application and then repeatedly replaying the recorded interaction. But users do not typically perform the same actions again and again. In this video we see how to extend and customize our automated Web tests to more accurately reflect the way a user would interact with the application. We learn how to create custom extraction rules to pull data from a Web control that the default extraction rules may not support, and how to add C# or Visual Basic-coded Web tests to add functionality such as looping, logic, and accessing external data.

Watch video (12 minutes)

PREVIOUS NEXT

The Effects of Caching

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

Nearly every Web application today needs to access data from a database, but this common operation can have a real impact on the overall performance of the application. This video illustrates how Visual Studio Team System can help you identify whether your application is making redundant calls to the database, and then demonstrates how you can employ ASP.NET 2.0 DataSource caching functionality to eliminate the redundant calls.

Watch video (15 minutes)

PREVIOUS NEXT

Using the Load Test Agent

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

In this video we examine how to incorporate the Load Test Agent in to the testing that we do with Visual Studio Team System. A Load Test Agent is part of a "rig" that can be deployed to separate machines to enable load, stress, and unit testing from another operating system or machine configuration. Each rig can work with several agents and can be deployed to virtual or remote machines, allowing for comprehensive testing with Visual Studio Team System.

Watch video (5 minutes)

PREVIOUS NEXT

The Effects of ViewState

2/20/2020 • 2 minutes to read • Edit Online

by Eric Lee

The ASP.NET framework provides the ViewState mechanism to automatically maintain application state by carrying data forward and backward between browser requests. In this video we see how some ASP.NET controls such as the DropDownList and TextBox maintain state based on postback form values rather than ViewState, allowing the smart developer to disable unnecessary ViewState. Using Visual Studio Team System we can see how this dramatically reduces the size of request and response data, and improves the performance and scalability of the application.

[How Do I:] Load Test a Web Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Menegay

This video walks you through the process of recording a Web Test and then replaying it as a Load Test that simulates multiple users. We see how Visual Studio Team System allows you to set warning and critical thresholds of server resources utilization, which defines whether the Web application passes or fails the load test.

Watch video (8 minutes)

PREVIOUS NEXT

[How Do I:] Tune Web Application Performance with Profiling?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Menegay

In this video we learn that Visual Studio Team System provides two methods of profiling a Web application: Sampling and Instrumentation. Instrumentation injects markers in the underlying code so that the developer can view full details of the application's execution, including call trees and object allocation, to help tune the performance of the application.

Watch video (8 minutes)

PREVIOUS NEXT

[How Do I:] Set Up Distributed Load Testing for High Volume Tests?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Menegay

Visual Studio Team System allows you to set up distibuted load testing by creating a test "rig" that comprises a Controller on one remote machine and multiple Agents on the same or additional remote machines. This video walks you through installing the Controller and the Agents, and then configurating your test cases to run using the remote Controller. As you will see, Visual Studio Team System makes it very simple to set up distributed load testing for high-volume automated testing.

Watch video (8 minutes)

PREVIOUS NEXT

[How Do I:] Enforce Coding Standards with Code Analysis?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Menegay

With Visual Studio Team System you have fine control over the code analysis rules that apply to class library projects, web site projects, and source code control. In this video we learn how to specify the errors and warnings that will apply during project builds and code check ins, and we see how to suppress a particular rule from applying to a specific class member. With this configurability you can enforce coding standards to improve the quality of your code, while ensuring inapplicable rules never get in your way.

Watch video (6 minutes)

PREVIOUS NEXT

[How Do I:] Use Generic Tests?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Menegay

A generic test is an existing program that is wrapped and made available as a test in Visual Studio Team System. In this video we see a demonstration of how a wrapped shell program accepts an input value from our test environment and how the program's output value is used to determine whether the test passed or failed.

Ajax Control Toolkit

2/20/2020 • 2 minutes to read • Edit Online

How to create very responsive ASP.NET Web pages using the Ajax Control Toolkit.

- Get Started with the ASP.NET AJAX Control Toolkit
- ASP.NET AJAX CascadingDropDown Control Extender
- ASP.NET AJAX TextBoxWatermark Control Extender
- ASP.NET AJAX Popup Control Extender
- ASP.NET AJAX ModalPopup Extender Control
- ASP.NET AJAX AlwaysVisible Control Extender
- ASP.NET AJAX Accordion Control
- ASP.NET AJAX Collapsable Panel Extender
- ASP.NET AJAX Draggable Panel Extender
- ASP.NET AJAX DynamicPopulate Extender
- ASP.NET AJAX FilteredTextbox Extender
- ASP.NET AJAX HoverMenu Extender
- ASP.NET AJAX ToggleButton Extender
- ASP.NET AJAX DropShadow Extender
- ASP.NET AJAX PasswordStrength Extender
- Get Started with the ASP.NET AJAX Animation Extender Control
- ASP.NET AJAX ConfirmButton Extender
- ASP.NET AJAX Slider Control
- ASP.NET AJAX AutoComplete Control
- Configure the ASP.NET AJAX Calendar Control
- ASP.NET AJAX DropDown Control
- ASP.NET AJAX MaskedEdit Controls
- ASP.NET AJAX MutuallyExclusive Checkbox Extender
- ASP.NET AJAX NoBot Control
- ASP.NET AJAX ListSearch Extender
- PagingBulletedList Extender Control
- NumericUpDown Extender Control
- ASP.NET AJAX ValidatorCallout Extender
- ASP.NET AJAX ResizableControl Extender
- ASP.NET AJAX Tabs Control
- ASP.NET AJAX SlideShow Extender
- ASP.NET AJAX UpdatePanelAnimation Extender
- AJAX Toolkit Reorder Control
- Utilize the AJAX Rating Control in the ASP.NET Toolkit
- Control Extenders
- Color Picker
- Combo Box
- Editor Control
- Editor Control Custom

- Create a New Custom Extender

[How Do I:] Get Started with the ASP.NET AJAX Control Toolkit?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

Learn how to extend your ASP.NET AJAX applications using the ASP.NET AJAX Control Toolkit. This video starts with the very basics, including downloading and installing the toolkit, and adding a few of its controls to a simple ASP.NET AJAX-enabled web page.

Watch video (11 minutes)

NEXT

[How Do I:] Use the ASP.NET AJAX CascadingDropDown Control Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

This video demonstrates how ASP.NET's standard DropDownList can become AJAX-enabled using the CascadingDropDown control extender from the ASP.NET AJAX Control Toolkit. You will also see how easy it is for a web form to draw its data from an XML Web Service.

Watch video (27 minutes)

by Joe Stagner

In this video we see a demonstration of the variety of options available to configure the appearance and the behavior of the Calendar extender control from the ASP.NET AJAX Control Toolkit.

Watch video (8 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX DropDown Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

With the DropDown control extender from the ASP.NET AJAX Control Toolkit, you can present the user with a drop-down list of options that trigger a partial-page update elsewhere on the Web page. The option selected by the user is passed to the server, allowing your server-side code to process the selection before completing the partial-page update.

Watch video (11 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX MaskedEdit Controls?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The ASP.NET AJAX Control Toolkit provides the MaskedEdit control and the MaskedEditValidator control which work together to prompt, style, and validate the data that the user enters in a text box. This allows the Web page to provide the user with immediate visual feedback on whether the data entered is of a valid type and format.

Watch video (17 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX MutuallyExclusive Checkbox Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The MutuallyExclusive control from the ASP.NET AJAX Control Toolkit enables the developer to configure a number of check boxes as mutually exclusive, which ensures the user may only check a single option. While a radio-button list provides similar behavior, the need for a check box to be clicked by the user makes the MutuallyExclusive control ideal for receiving confirmation from the user, such as accepting or not accepting terms of use.

Watch video (10 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX NoBot Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The NoBot control from the ASP.NET AJAX Control Toolkit helps prevent certain types of unauthorized access to your Web applications. In this video we see how the NoBot control provides a number of built-in guards against automated access, including checking the number and frequency of form submissions. We also see how the control allows the developer to define a custom challenge, such as a JavaScript test that will succeed only if the page is viewed in a browser.

Watch video (21 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX ListSearch Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

This video demonstrates the use of the ListSearch extender control from the ASP.NET AJAX Control Toolkit. The ListSearch extender enhances DropDownList and ListBox controls so that a user can select an item in the list by simply typing its first few characters. This enhancement improves the user experience by providing an intuitive way of selecting an item from a long list.

Watch video (11 minutes)

PREVIOUS NEXT

[How Do I:] Use the PagingBulletedList Extender Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

This video demonstrates the use of the PagingBulletedList extender control from the ASP.NET AJAX Control Toolkit. We learn how the PagingBulletedList extender adds client-side paging and sorting to the standard ASP.NET BulletedList control, which greatly improves the user experience when presenting an extensive list of items. We also see how we can define custom JavaScript and CSS to fully manage the user experience.

Watch video (25 minutes)

PREVIOUS NEXT

[How Do I:] Use the NumericUpDown Extender Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video we examine the NumericUpDown extender control from the ASP.NET AJAX Control Toolkit. We see how the NumericUpDown extender adds "up" and "down" buttons to a standard ASP.NET TextBox control. The buttons allow the user to increment or decrement a number, cycle through a list of known values, or call a Web Service to retrieve the next value. In this way the developer can fully control the values the user may submit to a Web application.

Watch video (21 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX ValidatorCallout Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The standard ASP.NET validation controls work on both the server and the client. Server-side validation adds to the security of your Web application, while client-side validation adds to the user friendliness of your Web application. This video demonstrates how the ValidatorCallout control from the ASP.NET AJAX Control Toolkit extends the standard validation controls to enhance the user experience by neatly positioning validation messages in callout boxes.

Watch video (11 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX ResizableControl Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The ResizableControl extender from the ASP.NET AJAX Control Toolkit allows the developer to specify a region of the Web page that the user may resize dynamically. This video demonstrates how to configure the look and feel of the resizable region, and how to run client-side script upon resizing.

Watch video (30 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX Tabs Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

This video demonstrates the basics of the Tabs control from the ASP.NET AJAX Control Toolkit, with which you can create a set of tabs to organize content on a Web page. The selected tab is maintained across post backs, making the Tabs control ideal for form-based administration pages.

Watch video (8 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX SlideShow Extender?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

This video demonstrates how the SlideShow extender from the ASP.NET AJAX Control Toolkit turns the standard ASP.NET Image control in to a fully-functional slide show. We also see how an ASP.NET Web service can return not only text and XML data but complete AJAX objects to be consumed by the ASP.NET AJAX Web application. Joe also comments on the benefits of storing images in the file system rather than the database.

Ways to work with ASP.NET AJAX to create highly responsive pages, even if you're not a JavaScript expert.

- Get Started with ASP.NET AJAX
- Implement Dynamic Partial-Page Updates with ASP.NET AJAX
- Make Client-Side Network Callbacks with ASP.NET AJAX
- Add ASP.NET AJAX Features to an Existing Web Application
- ASP.NET AJAX Enable an Existing Web Service
- ASP.NET AJAX Client Library Controls
- Use an ASP.NET AJAX ScriptManagerProxy
- ASP.NET AJAX RoundedCorners Extender
- ASP.NET AJAX Timer Control
- Implement the Predictive Fetch Pattern for AJAX
- Implement the AJAX Paging Pattern
- Implement the AJAX Incremental Page Display Pattern
- Implement the Incremental Page Display Pattern using HTTP GET and POST
- ASP.NET AJAX UpdateProgress Control
- ASP.NET AJAX History Control
- Implement the AJAX After Processing Pattern
- Update Multiple Regions of a Page with ASP.NET AJAX
- Choose Between Methods of AJAX Page Updates
- Use Other JavaScript User Interface Libraries with ASP.NET AJAX
- Use the ASP.NET AJAX Profile Services
- Debug ASP.NET AJAX Applications Using Visual Studio 2005
- Build a Custom ASP.NET AJAX Server Control
- Use JavaScript to Refresh an ASP.NET AJAX UpdatePanel
- Determine Whether an Asynchronous Postback has Occurred
- Use the Conditional UpdateMode of the UpdatePanel
- Implement the Persistent Communications Pattern with the UpdatePanel
- Localize an ASP.NET AJAX Application
- Implement the Persistent Communications Pattern using Web Services
- Trigger an UpdatePanel Refresh from a DropDownList Control
- Create an ASP.NET AJAX Extender from Scratch
- Build Custom Server Controls that Work With or Without ASP.NET AJAX
- Associate AJAX Client Behavior with an ASP.NET Server Control
- Retrieve Values From Server Side AJAX Controls
- Two Simple Techniques for Triggering Updates to Update Panels
- Use ASP.NET AJAX Cascading Drop Down Control to Access a Database
- Implement Infinite Data Patterns in AJAX
- Basic ASP.NET Authentication in an AJAX Enabled Application
- Dynamically Change CSS ASP.NET AJAX UpdatePanel
- Dynamically Add Controls to a Web Page

- Set Up Your Development Environment for ASP.NET 3.5
- Set Up Your Development Environment for ASP.NET 2.0
- Customize Error Handling for the ASP.NET AJAX UpdatePanel
- Use ASP.NET AJAX Client Templates

[How Do I:] Get Started with ASP.NET AJAX?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

Note that ASP.NET AJAX is included as part of .NET 3.5, so the installation part of this video is only relevant if you are using the .NET Framework Version 2.0.

[How Do I:] Use the ASP.NET AJAX UpdateProgress Control?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In an AJAX application there is often a noticeable pause between the time the browser makes a network request and the time the browser receives a response. To let the user know that the network conversation is taking place, the ASP.NET AJAX UpdateProgress control provides immediate feedback by displaying an animated image, 'loading' text, or other HTML that disappears once the network response is received.

Watch video (6 minutes)

PREVIOUS NEXT

[How Do I:] Use the ASP.NET AJAX History Control?

2/20/2020 • 2 minutes to read • Edit Online

by Scott Golightly

One problem faced by a typical AJAX application is that a partial page update is not added to the history of the Web browser. This means that the browser's Back button does not move back one AJAX step, but moves back one entire document, which is unlikely to be what the user expects. The ASP.NET AJAX History control allows the developer to insert history points so that the user may click the browser's Back and Forward buttons to move between AJAX steps.

[How Do I:] Update Multiple Regions of a Page with ASP.NET AJAX?

2/20/2020 • 2 minutes to read • Edit Online

by Scott Golightly

In this video we learn that the ASP.NET AJAX UpdatePanel control provides two properties that you may use to update multiple regions of a Web page in response to a single client-side event. The UpdateMode property may be set to Always, in which case the panel will always update during a post back, or set to Conditional, in which case the panel will only update in response to specific events. The Triggers collection property allows you to specify those events that will cause the panel to update. Used together these properties allow multiple UpdatePanel controls to update in response to the same event trigger.

[How Do I:] Choose Between Methods of AJAX Page Updates?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video Joe Stagner compares the two primary methods of performing AJAX-style page updates in an ASP.NET application. The first method is to use an UpdatePanel, where no additional code needs to be written on either the client side or the server side. The benefit of using the UpdatePanel is that everything works automatically. The penalty is that at the client it requires a lot of data to be included in the AJAX request and response, and at the server it requires a full page lifecycle to be executed. The second method is to use network callbacks, where additional code needs to be written on both the client side and the server side. The benefit of using network callbacks is that at the client it requires very little data to be included in the AJAX request and response, and at the server it requires only the called service method to be executed. The penality is the time and effort it takes to write the necessary code. Joe concludes the video by discussing what you should consider when choosing between the two primary methods of AJAX-style page updates. (This video uses the code from the How Do I Get Started with ASP.NET AJAX video and the How Do I Make Client-Side Network Callbacks with ASP.NET AJAX video.)

[How Do I:] Use the ASP.NET AJAX Profile Services?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

ASP.NET 2.0 introduced Profile properties with which you can store details for each user of your ASP.NET Web application. ASP.NET AJAX Profile Services allow your client-side Web interface to retrieve a user's Profile properties from the server-side Web application. This video demonstrates how a sample AJAX-enabled travel site can store the travel request information of a user so that the details can be retrieved when he or she next visits the site.

[How Do I:] Use JavaScript to Refresh an ASP.NET AJAX UpdatePanel?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In this video we learn two different ways of using JavaScript logic to refresh the content of an ASP.NET AJAX UpdatePanel control. The first way is to add a Button-type server control to the UpdatePanel and use JavaScript to trigger an asynchronous postback and 'pretend' that the postback was caused by the server control inside the UpdatePanel. The second way does not require any Button-type server control to be added to the UpdatePanel, but still allows us to use JavaScript logic to refresh the content of the UpdatePanel. (The second technique was suggested by Dave Ward and you can read more on his weblog entry, " Easily refresh an UpdatePanel, using JavaScript ".)

[How Do I:] Use the Conditional UpdateMode of the UpdatePanel?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

The ASP.NET AJAX UpdatePanel includes an UpdateMode property that may be set to 'Always' or 'Conditional'. The default is Always, in which case the UpdatePanel will always update its content during an asynchronous postback. In this video we learn how we can set the UpdateMode to Conditional, in which case the UpdatePanel will only update its content when our server-side code calls its Update method. This allows you to use conditional logic in your C# or Visual Basic code to determine whether the UpdatePanel will update its content during the current asynchronous postback.

[How Do I:] Implement the Persistent Communications Pattern with the UpdatePanel?

2/20/2020 • 2 minutes to read • Edit Online

by Joe Stagner

In a traditional Web site the browser and the server do not maintain an ongoing communication, but communicate only in response to the user performing an action. In a modern Web site where the page becomes an application container, it can be advantageous for the browser and the server to maintain an ongoing communication so that page updates can occur without the user performing an action. This is known as the Persistent Communications Pattern for AJAX. ASP.NET AJAX provides two main ways for Web developers to implement the Persistent Communications Pattern. This video demonstrates the simple way, which is to use the ASP.NET AJAX UpdatePanel as the basis of the implementation. In a later video we will learn how to implement the same pattern without the use of the ASP.NET AJAX UpdatePanel.

How Do I: Make Ajax Calls Using jQuery?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to make Ajax calls using the jQuery library. A sample web site is created that contains a simple web service which returns a value. Next, the jQuery ajax() method is used to call the web service. A number of the ajax() method options are set including url, dataType, data, etc. In addition, event handlers for both success and error conditions are defined. Another web services is then defined which accepts an argument and also returns a value. A second ajax() call is defined that passes a value to the web service call and processes the return data. Finally, the setup for global options and event handlers for ajax() method calls are discussed.

How Do I: Use Routing with ASP.NET Web Forms?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to implement routing for Web Forms in ASP.NET 4. First, the concept of routing a URL is compared to mapping the URL to a physical file in the site. Then, a sample route for a URL is defined in the global.asax file Application_Start event handler. The route contains a parameterized value that the user can enter in the URL. A sample page is then created and the route parameter value is extracted in the Page_Load event handler. Next, a second route is defined that has multiple parameters and routes to the same page as the initial route. The Page_Load event handler is expanded to extract the additional route parameter value and display different information depending upon what values have been passed to the page.

PREVIOUS NEXT

How Do I: Work with URLs in ASP.NET Routing?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to specify URLs in a web site that utilizes ASP.NET routing. First, a web site is created and routing is defined in the Global Application Class (.asax). Next, a sample web page is created and a URL based upon a defined route is added to the page using the standard "hard coded" approach, e.g., "~/Stats/Visitors". Another link is then added to the page which dynamically generates the same URL in markup using the RouteValue method which accepts the route name and parameters. The same URL is then implemented using code rather than markup directly in the page. The original route and physical page location are then changed, resulting in the hard coded link no longer working whereas both dynamically generated links function properly. Finally, the value of dynamically generated links is then discussed.

What is Web Forms

2/20/2020 • 11 minutes to read • Edit Online

ASP.NET Web Forms is a part of the ASP.NET web application framework and is included with Visual Studio. It is one of the four programming models you can use to create ASP.NET web applications, the others are ASP.NET MVC, ASP.NET Web Pages, and ASP.NET Single Page Applications.

Web Forms are pages that your users request using their browser. These pages can be written using a combination of HTML, client-script, server controls, and server code. When users request a page, it is compiled and executed on the server by the framework, and then the framework generates the HTML markup that the browser can render. An ASP.NET Web Forms page presents information to the user in any browser or client device.

Using Visual Studio, you can create ASP.NET Web Forms. The Visual Studio Integrated Development Environment (IDE) lets you drag and drop server controls to lay out your Web Forms page. You can then easily set properties, methods, and events for controls on the page or for the page itself. These properties, methods, and events are used to define the web page's behavior, look and feel, and so on. To write server code to handle the logic for the page, you can use a .NET language like Visual Basic or C#.

> **NOTE**
>
> ASP.NET and Visual Studio documentation spans several versions. Topics that highlight features from previous versions may be useful for your current tasks and scenarios using the latest versions.

ASP.NET Web Forms are:

- Based on Microsoft ASP.NET technology, in which code that runs on the server dynamically generates Web page output to the browser or client device.
- Compatible with any browser or mobile device. An ASP.NET Web page automatically renders the correct browser-compliant HTML for features such as styles, layout, and so on.
- Compatible with any language supported by the .NET common language runtime, such as Microsoft Visual Basic and Microsoft Visual C#.
- Built on the Microsoft .NET Framework. This provides all the benefits of the framework, including a managed environment, type safety, and inheritance.
- Flexible because you can add user-created and third party controls to them.

ASP.NET Web Forms offer:

- Separation of HTML and other UI code from application logic.
- A rich suite of server controls for common tasks, including data access.
- Powerful data binding, with great tool support.
- Support for client-side scripting that executes in the browser.
- Support for a variety of other capabilities, including routing, security, performance, internationalization, testing, debugging, error handling and state management.

ASP.NET Web Forms Helps You Overcome Challenges

Web application programming presents challenges that do not typically arise when programming traditional client-based applications. Among the challenges are:

- **Implementing a rich Web user interface** - It can be difficult and tedious to design and implement a user

interface using basic HTML facilities, especially if the page has a complex layout, a large amount of dynamic content, and full-featured user-interactive objects.

- **Separation of client and server** - In a Web application, the client (browser) and server are different programs often running on different computers (and even on different operating systems). Consequently, the two halves of the application share very little information; they can communicate, but typically exchange only small chunks of simple information.
- **Stateless execution** - When a Web server receives a request for a page, it finds the page, processes it, sends it to the browser, and then discards all page information. If the user requests the same page again, the server repeats the entire sequence, reprocessing the page from scratch. Put another way, a server has no memory of pages that it has processed—page are stateless. Therefore, if an application needs to maintain information about a page, its stateless nature can become a problem.
- **Unknown client capabilities** - In many cases, Web applications are accessible to many users using different browsers. Browsers have different capabilities, making it difficult to create an application that will run equally well on all of them.
- **Complications with data access** - Reading from and writing to a data source in traditional Web applications can be complicated and resource-intensive.
- **Complications with scalability** - In many cases Web applications designed with existing methods fail to meet scalability goals due to the lack of compatibility between the various components of the application. This is often a common failure point for applications under a heavy growth cycle.

Meeting these challenges for Web applications can require substantial time and effort. ASP.NET Web Forms and the ASP.NET framework address these challenges in the following ways:

- **Intuitive, consistent object model** - The ASP.NET page framework presents an object model that enables you to think of your forms as a unit, not as separate client and server pieces. In this model, you can program the page in a more intuitive way than in traditional Web applications, including the ability to set properties for page elements and respond to events. In addition, ASP.NET server controls are an abstraction from the physical contents of an HTML page and from the direct interaction between browser and server. In general, you can use server controls the way you might work with controls in a client application and not have to think about how to create the HTML to present and process the controls and their contents.
- **Event-driven programming model** - ASP.NET Web Forms bring to Web applications the familiar model of writing event handlers for events that occur on either the client or server. The ASP.NET page framework abstracts this model in such a way that the underlying mechanism of capturing an event on the client, transmitting it to the server, and calling the appropriate method is all automatic and invisible to you. The result is a clear, easily written code structure that supports event-driven development.
- **Intuitive state management** - The ASP.NET page framework automatically handles the task of maintaining the state of your page and its controls, and it provides you with explicit ways to maintain the state of application-specific information. This is accomplished without heavy use of server resources and can be implemented with or without sending cookies to the browser.
- **Browser-independent applications** - The ASP.NET page framework enables you to create all application logic on the server, eliminating the need to explicitly code for differences in browsers. However, it still enables you to take advantage of browser-specific features by writing client-side code to provide improved performance and a richer client experience.
- **.NET Framework common language runtime support** - The ASP.NET page framework is built on the .NET Framework, so the entire framework is available to any ASP.NET application. Your applications can be written in any language that is compatible that is with the runtime. In addition, data access is simplified using the data access infrastructure provided by the .NET Framework, including ADO.NET.
- **.NET Framework scalable server performance** - The ASP.NET page framework enables you to scale your Web application from one computer with a single processor to a multi-computer Web farm cleanly and without complicated changes to the application's logic.

Features of ASP.NET Web Forms

- **Server Controls**- ASP.NET Web server controls are objects on ASP.NET Web pages that run when the page is requested and that render markup to the browser. Many Web server controls are similar to familiar HTML elements, such as buttons and text boxes. Other controls encompass complex behavior, such as a calendar controls, and controls that you can use to connect to data sources and display data.
- **Master Pages**- ASP.NET master pages allow you to create a consistent layout for the pages in your application. A single master page defines the look and feel and standard behavior that you want for all of the pages (or a group of pages) in your application. You can then create individual content pages that contain the content you want to display. When users request the content pages, they merge with the master page to produce output that combines the layout of the master page with the content from the content page.
- **Working with Data**- ASP.NET provides many options for storing, retrieving, and displaying data. In an ASP.NET Web Forms application, you use data-bound controls to automate the presentation or input of data in web page UI elements such as tables and text boxes and drop-down lists.
- **Membership**- ASP.NET Identity stores your users' credentials in a database created by the application. When your users log in, the application validates their credentials by reading the database. Your project's *Account* folder contains the files that implement the various parts of membership: registering, logging in, changing a password, and authorizing access. Additionally, ASP.NET Web Forms supports OAuth and OpenID. These authentication enhancements allow users to log into your site using existing credentials, from such accounts as Facebook, Twitter, Windows Live, and Google. By default, the template creates a membership database using a default database name on an instance of SQL Server Express LocalDB, the development database server that comes with Visual Studio Express 2013 for Web.
- **Client Script and Client Frameworks**- You can enhance the server-based features of ASP.NET by including client-script functionality in ASP.NET Web Form pages. You can use client script to provide a richer, more responsive user interface to users. You can also use client script to make asynchronous calls to the Web server while a page is running in the browser.
- **Routing**- URL routing allows you to configure an application to accept request URLs that do not map to physical files. A request URL is simply the URL a user enters into their browser to find a page on your web site. You use routing to define URLs that are semantically meaningful to users and that can help with search-engine optimization (SEO).
- **State Management**- ASP.NET Web Forms includes several options that help you preserve data on both a per-page basis and an application-wide basis.
- **Security**- An important part of developing a more secure application is to understand the threats to it. Microsoft has developed a way to categorize threats: Spoofing, Tampering, Repudiation, Information disclosure, Denial of service, Elevation of privilege (STRIDE). In ASP.NET Web Forms, you can add extensibility points and configuration options that enable you to customize various security behaviors in ASP.NET Web Forms.
- **Performance**- Performance can be a key factor in a successful Web site or project. ASP.NET Web Forms allows you to modify performance related to page and server control processing, state management, data access, application configuration and loading, and efficient coding practices.
- **Internationalization**- ASP.NET Web Forms enables you to create web pages that can obtain content and other data based on the preferred language setting for the browser or based on the user's explicit choice of language. Content and other data is referred to as resources and such data can be stored in resource files or other sources. In an ASP.NET Web Forms page, you configure controls to get their property values from resources. At run time, the resource expressions are replaced by resources from the appropriate localized resource file.
- **Debugging and Error Handling**- ASP.NET includes features to help you diagnose problems that might arise in your Web Forms application. Debugging and error handling are well supported within ASP.NET Web Forms so that your applications compile and run effectively.
- **Deployment and Hosting**- Visual Studio, ASP.NET, Azure, and IIS provide tools that help you with the process of deploying and hosting your Web Forms application.

Deciding When to Create a Web Forms Application

You must consider carefully whether to implement a Web application by using either the ASP.NET Web Forms model or another model, such as the ASP.NET MVC framework. The MVC framework does not replace the Web Forms model; you can use either framework for Web applications. Before you decide to use the Web Forms model or the MVC framework for a specific Web site, weigh the advantages of each approach.

Advantages of a Web Forms-Based Web Application

The Web Forms-based framework offers the following advantages:

- It supports an event model that preserves state over HTTP, which benefits line-of-business Web application development. The Web Forms-based application provides dozens of events that are supported in hundreds of server controls.
- It uses a Page Controller pattern that adds functionality to individual pages. For more information, see Page Controller on the MSDN Web site.
- It uses view state or server-based forms, which can make managing state information easier.
- It works well for small teams of Web developers and designers who want to take advantage of the large number of components available for rapid application development.
- In general, it is less complex for application development, because the components (the **Page** class, controls, and so on) are tightly integrated and usually require less code than the MVC model.

Advantages of an MVC-Based Web Application

The ASP.NET MVC framework offers the following advantages:

- It makes it easier to manage complexity by dividing an application into the model, the view, and the controller.
- It does not use view state or server-based forms. This makes the MVC framework ideal for developers who want full control over the behavior of an application.
- It uses a Front Controller pattern that processes Web application requests through a single controller. This enables you to design an application that supports a rich routing infrastructure. For more information, see Front Controller on the MSDN Web site.
- It provides better support for test-driven development (TDD).
- It works well for Web applications that are supported by large teams of developers and Web designers who need a high degree of control over the application behavior.

Getting started with ASP.NET MVC 5

2/21/2020 • 3 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

This tutorial teaches you the basics of building an ASP.NET MVC 5 web app using Visual Studio 2017. The final source code for the tutorial is located on GitHub.

This tutorial was written by Scott Guthrie (twitter@scottgu), Scott Hanselman (twitter: @shanselman), and Rick Anderson (@RickAndMSFT)

You need an Azure account to deploy this app to Azure:

- You can open an Azure account for free - You get credits you can use to try out paid Azure services, and even after they're used up you can keep the account and use free Azure services.
- You can activate MSDN subscriber benefits - Your MSDN subscription gives you credits every month that you can use for paid Azure services.

Get started

Start by installing Visual Studio 2017. Then, open Visual Studio.

Visual Studio is an IDE, or integrated development environment. Just like you use Microsoft Word to write documents, you'll use an IDE to create applications. In Visual Studio, there's a list along the bottom showing various options available to you. There's also a menu that provides another way to perform tasks in the IDE. For example, instead of selecting **New Project** on the **Start page**, you can use the menu bar and select **File** > **New Project**.

Create your first app

On the **Start page**, select **New Project**. In the **New project** dialog box, select the **Visual C#** category on the left, then **Web**, and then select the **ASP.NET Web Application (.NET Framework)** project template. Name your project "MvcMovie" and then choose **OK**.

In the **New ASP.NET Web Application** dialog, choose **MVC** and then choose **OK**.

Visual Studio used a default template for the ASP.NET MVC project you just created, so you have a working application right now without doing anything! This is a simple "Hello World!" project, and it's a good place to start your application.

Press **F5** to start debugging. When you press **F5**, Visual Studio starts IIS Express and runs your web app. Visual Studio then launches a browser and opens the application's home page. Notice that the address bar of the browser says `localhost:port#` and not something like `example.com`. That's because `localhost` always points to your own local computer, which in this case is running the application you just built. When Visual Studio runs a web project, a random port is used for the web server. In the image below, the port number is 1234. When you run the application, you'll see a different port number.

Right out of the box this default template gives you `Home`, `Contact`, and `About` pages. The image below doesn't show the **Home**, **About**, and **Contact** links. Depending on the size of your browser window, you might need to click the navigation icon to see these links.

The application also provides support to register and log in. The next step is to change how this application works and learn a little bit about ASP.NET MVC. Close the ASP.NET MVC application and let's change some code.

For a list of current tutorials, see MVC recommended articles.

See this app running on Azure

Would you like to see the finished site running as a live web app? You can deploy a complete version of the app to your Azure account by simply clicking the following button.

Deploy to Azure

You need an Azure account to deploy this solution to Azure. If you don't already have an account, use one of the following options to create one:

- Open an Azure account for free - You get credits you can use to try out paid Azure services, and even after they're used up you can keep the account and use free Azure services.
- Activate Visual Studio subscriber benefits - Your Visual Studio subscription gives you credits every month that you can use for paid Azure services.

NEXT

Adding a Controller

9/16/2020 • 6 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

MVC stands for *model-view-controller*. MVC is a pattern for developing applications that are well architected, testable and easy to maintain. MVC-based applications contain:

- **M** odels: Classes that represent the data of the application and that use validation logic to enforce business rules for that data.
- **V** iews: Template files that your application uses to dynamically generate HTML responses.
- **C** ontrollers: Classes that handle incoming browser requests, retrieve model data, and then specify view templates that return a response to the browser.

We'll be covering all these concepts in this tutorial series and show you how to use them to build an application.

Let's begin by creating a controller class. In **Solution Explorer**, right-click the *Controllers* folder and then click **Add**, then **Controller**.

In the **Add Scaffold** dialog box, click **MVC 5 Controller - Empty**, and then click **Add**.

Name your new controller "HelloWorldController" and click **Add**.

Notice in **Solution Explorer** that a new file has been created named *HelloWorldController.cs* and a new folder *Views\HelloWorld*. The controller is open in the IDE.

Replace the contents of the file with the following code.

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my <b>default</b> action...";
        }

        //
        // GET: /HelloWorld/Welcome/

        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

The controller methods will return a string of HTML as an example. The controller is named `HelloWorldController` and the first method is named `Index`. Let's invoke it from a browser. Run the application (press F5 or Ctrl+F5). In the browser, append "HelloWorld" to the path in the address bar. (For example, in the illustration below, it's `http://localhost:1234/HelloWorld.`) The page in the browser will look like the following screenshot. In the method above, the code returned a string directly. You told the system to just return some HTML, and it did!

ASP.NET MVC invokes different controller classes (and different action methods within them) depending on the incoming URL. The default URL routing logic used by ASP.NET MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

You set the format for routing in the *App_Start/RouteConfig.cs* file.

```
public static void RegisterRoutes(RouteCollection routes)
{
    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        name: "Default",
        url: "{controller}/{action}/{id}",
        defaults: new { controller = "Home", action = "Index", id = UrlParameter.Optional }
    );
}
```

When you run the application and don't supply any URL segments, it defaults to the "Home" controller and the "Index" action method specified in the defaults section of the code above.

The first part of the URL determines the controller class to execute. So */HelloWorld* maps to the `HelloWorldController` class. The second part of the URL determines the action method on the class to execute. So */HelloWorld/Index* would cause the `Index` method of the `HelloWorldController` class to execute. Notice that we only had to browse to */HelloWorld* and the `Index` method was used by default. This is because a method named `Index` is the default method that will be called on a controller if one is not explicitly specified. The third part of the URL segment (`Parameters`) is for route data. We'll see route data later on in this tutorial.

Browse to `http://localhost:xxxx/HelloWorld/Welcome`. The `Welcome` method runs and returns the string "This is the Welcome action method...". The default MVC mapping is `/[Controller]/[ActionName]/[Parameters]`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.

Let's modify the example slightly so that you can pass some parameter information from the URL to the controller (for example, */HelloWorld/Welcome?name=Scott&numtimes=4*). Change your `Welcome` method to include two parameters as shown below. Note that the code uses the C# optional-parameter feature to indicate that the `numTimes` parameter should default to 1 if no value is passed for that parameter.

```
public string Welcome(string name, int numTimes = 1) {
     return HttpUtility.HtmlEncode("Hello " + name + ", NumTimes is: " + numTimes);
}
```

NOTE

Security Note: The code above uses HttpUtility.HtmlEncode to protect the application from malicious input (namely JavaScript). For more information see How to: Protect Against Script Exploits in a Web Application by Applying HTML Encoding to Strings.

Run your application and browse to the example URL (`http://localhost:xxxx/HelloWorld/Welcome?name=Scott&numtimes=4`). You can try different values for `name` and `numtimes` in the URL. The ASP.NET MVC model binding system automatically maps the named parameters from

the query string in the address bar to parameters in your method.

Hello Scott, NumTimes is: 4

In the sample above, the URL segment (`Parameters`) is not used, the `name` and `numTimes` parameters are passed as query strings. The ? (question mark) in the above URL is a separator, and the query strings follow. The & character separates query strings.

Replace the Welcome method with the following code:

```
public string Welcome(string name, int ID = 1)
{
    return HttpUtility.HtmlEncode("Hello " + name + ", ID: " + ID);
}
```

Run the application and enter the following URL: `http://localhost:xxx/HelloWorld/Welcome/1?name=Scott`

Hello Scott, ID: 1

This time the third URL segment matched the route parameter `ID.` The `Welcome` action method contains a parameter (`ID`) that matched the URL specification in the `RegisterRoutes` method.

```
public static void RegisterRoutes(RouteCollection routes)
{
    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        name: "Default",
        url: "{controller}/{action}/{id}",
        defaults: new { controller = "Home", action = "Index", id = UrlParameter.Optional }
    );
}
```

In ASP.NET MVC applications, it's more typical to pass in parameters as route data (like we did with ID above) than passing them as query strings. You could also add a route to pass both the `name` and `numtimes` in parameters as route data in the URL. In the *App_Start\RouteConfig.cs* file, add the "Hello" route:

```
public class RouteConfig
{
   public static void RegisterRoutes(RouteCollection routes)
   {
      routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

      routes.MapRoute(
          name: "Default",
          url: "{controller}/{action}/{id}",
          defaults: new { controller = "Home", action = "Index", id = UrlParameter.Optional }
      );

      routes.MapRoute(
           name: "Hello",
           url: "{controller}/{action}/{name}/{id}"
       );
   }
}
```

Run the application and browse to `/localhost:XXX/HelloWorld/Welcome/Scott/3`.

For many MVC applications, the default route works fine. You'll learn later in this tutorial to pass data using the model binder, and you won't have to modify the default route for that.

In these examples the controller has been doing the "VC" portion of MVC — that is, the view and controller work. The controller is returning HTML directly. Ordinarily you don't want controllers returning HTML directly, since that becomes very cumbersome to code. Instead we'll typically use a separate view template file to help generate the HTML response. Let's look next at how we can do this.

PREVIOUS NEXT

Adding a View

9/16/2020 • 9 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section you're going to modify the `HelloWorldController` class to use view template files to cleanly encapsulate the process of generating HTML responses to a client.

You'll create a view template file using the Razor view engine. Razor-based view templates have a *.cshtml* file extension, and provide an elegant way to create HTML output using C#. Razor minimizes the number of characters and keystrokes required when writing a view template, and enables a fast, fluid coding workflow.

Currently the `Index` method returns a string with a message that is hard-coded in the controller class. Change the `Index` method to call the controllers View method, as shown in the following code:

```
public ActionResult Index()
{
    return View();
}
```

The `Index` method above uses a view template to generate an HTML response to the browser. Controller methods (also known as action methods), such as the `Index` method above, generally return an ActionResult (or a class derived from ActionResult), not primitive types like string.

Right click the *Views\HelloWorld* folder and click **Add**, then click **MVC 5 View Page with Layout (Razor)**.

In the **Specify Name for Item** dialog box, enter *Index*, and then click **OK**.

In the **Select a Layout Page** dialog, accept the default **_Layout.cshtml** and click **OK**.

In the dialog above, the *Views\Shared* folder is selected in the left pane. If you had a custom layout file in another folder, you could select it. We'll talk about the layout file later in the tutorial

The *MvcMovie\Views\HelloWorld\Index.cshtml* file is created.

Add the following highlighted markup.

```
@{
    Layout = "~/Views/Shared/_Layout.cshtml";
}

@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Right click the *Index.cshtml* file and select **View in Browser**.

You can also right click the *Index.cshtml* file and select **View in Page Inspector.** See the Page Inspector tutorial for more information.

Alternatively, run the application and browse to the `HelloWorld` controller (`http://localhost:xxxx/HelloWorld`). The `Index` method in your controller didn't do much work; it simply ran the statement `return View()`, which specified that the method should use a view template file to render a response to the browser. Because you didn't explicitly specify the name of the view template file to use, ASP.NET MVC defaulted to using the *Index.cshtml* view file in the *\Views\HelloWorld* folder. The image below shows the string "Hello from our View Template!" hard-coded in the view.

Looks pretty good. However, notice that the browser's title bar shows "Index - My ASP.NET Application," and the big link at the top of the page says "Application name." Depending on how small you make your browser window, you might need to click the three bars in the upper right to see the to the **Home**, **About**, **Contact**, **Register** and **Log in** links.

Changing Views and Layout Pages

First, you want to change the "Application name" link at the top of the page. That text is common to every page. It's actually implemented in only one place in the project, even though it appears on every page in the application. Go to the */Views/Shared* folder in **Solution Explorer** and open the *_Layout.cshtml* file. This file is called a *layout page* and it's in the shared folder that all other pages use.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, "wrapped" in the layout page. For example, if you select the **About** link, the *Views\Home\About.cshtml* view is rendered inside the `RenderBody` method.

Change the contents of the title element. Change the ActionLink in the layout template from "Application name" to "MVC Movie" and the controller from `Home` to `Movies`. The complete layout file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - Movie App</title>
    @Styles.Render("~/Content/css")
    @Scripts.Render("~/bundles/modernizr")

</head>
<body>
    <div class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                @Html.ActionLink("MVC Movie", "Index", "Movies", null, new { @class = "navbar-brand" })
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li>@Html.ActionLink("Home", "Index", "Home")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                    <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
                </ul>
            </div>
        </div>
    </div>
    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; @DateTime.Now.Year - My ASP.NET Application</p>
        </footer>
    </div>

    @Scripts.Render("~/bundles/jquery")
    @Scripts.Render("~/bundles/bootstrap")
    @RenderSection("scripts", required: false)
</body>
</html>
```

Run the application and notice that it now says "MVC Movie ". Click the **About** link, and you see how that page shows "MVC Movie", too. We were able to make the change once in the layout template and have all pages on the site reflect the new title.

When we first created the *Views\HelloWorld\Index.cshtml* file, it contained the following code:

```
@{
    Layout = "~/Views/Shared/_Layout.cshtml";
}
```

The Razor code above is explicitly setting the layout page. Examine the *Views_ViewStart.cshtml* file, it contains the exact same Razor markup. The *Views_ViewStart.cshtml* file defines the common layout that all views will use, therefore you can comment out or remove that code from the *Views\HelloWorld\Index.cshtml* file.

```
@*@{
    Layout = "~/Views/Shared/_Layout.cshtml";
}*@

@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

You can use the `Layout` property to set a different layout view, or set it to `null` so no layout file will be used.

Now, let's change the title of the Index view.

Open *MvcMovie\Views\HelloWorld\Index.cshtml*. There are two places to make a change: first, the text that appears in the title of the browser, and then in the secondary header (the `<h2>` element). You'll make them slightly different so you can see which bit of code changes which part of the app.

```
@{
    ViewBag.Title = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

To indicate the HTML title to display, the code above sets a `Title` property of the `ViewBag` object (which is in the *Index.cshtml* view template). Notice that the layout template (*Views\Shared_Layout.cshtml*) uses this value in the `<title>` element as part of the `<head>` section of the HTML that we modified previously.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - Movie App</title>
    @Styles.Render("~/Content/css")
    @Scripts.Render("~/bundles/modernizr")
</head>
```

Using this `ViewBag` approach, you can easily pass other parameters between your view template and your layout file.

Run the application. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with the `ViewBag.Title` we set in the *Index.cshtml* view template and the additional "- Movie App" added in the layout file.

Also notice how the content in the *Index.cshtml* view template was merged with the *_Layout.cshtml* view template and a single HTML response was sent to the browser. Layout templates make it really easy to make changes that apply across all of the pages in your application.

Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet. Shortly, we'll walk through how to create a database and retrieve model data from it.

Passing Data from the Controller to the View

Before we go to a database and talk about models, though, let's first talk about passing information from the controller to a view. Controller classes are invoked in response to an incoming URL request. A controller class is

where you write the code that handles the incoming browser requests, retrieves data from a database, and ultimately decides what type of response to send back to the browser. View templates can then be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing whatever data or objects are required in order for a view template to render a response to the browser. A best practice: **A view template should never perform business logic or interact with a database directly**. Instead, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep your code clean, testable and more maintainable.

Currently, the `Welcome` action method in the `HelloWorldController` class takes a `name` and a `numTimes` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, let's change the controller to use a view template instead. The view template will generate a dynamic response, which means that you need to pass appropriate bits of data from the controller to the view in order to generate the response. You can do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewBag` object that the view template can then access.

Return to the *HelloWorldController.cs* file and change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewBag` object. `ViewBag` is a dynamic object, which means you can put whatever you want in to it; the `ViewBag` object has no defined properties until you put something inside it. The ASP.NET MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult Welcome(string name, int numTimes = 1)
        {
            ViewBag.Message = "Hello " + name;
            ViewBag.NumTimes = numTimes;

            return View();
        }
    }
}
```

Now the `ViewBag` object contains data that will be passed to the view automatically. Next, you need a Welcome view template! In the **Build** menu, select **Build Solution** (or Ctrl+Shift+B) to make sure the project is compiled. Right click the *Views\HelloWorld* folder and click **Add**, then click **MVC 5 View Page with Layout (Razor)**.

In the **Specify Name for Item** dialog box, enter *Welcome*, and then click **OK**.

In the **Select a Layout Page** dialog, accept the default **_Layout.cshtml** and click **OK**.

The *MvcMovie\Views\HelloWorld\Welcome.cshtml* file is created.

Replace the markup in the *Welcome.cshtml* file. You'll create a loop that says "Hello" as many times as the user says it should. The complete *Welcome.cshtml* file is shown below.

```
@{
    ViewBag.Title = "Welcome";
}

<h2>Welcome</h2>

<ul>
    @for (int i = 0; i < ViewBag.NumTimes; i++)
    {
        <li>@ViewBag.Message</li>
    }
</ul>
```

Run the application and browse to the following URL:

`http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4`

Now data is taken from the URL and passed to the controller using the model binder. The controller packages the data into a `ViewBag` object and passes that object to the view. The view then displays the data as HTML to the user.

In the sample above, we used a `ViewBag` object to pass data from the controller to a view. Later in the tutorial, we will use a view model to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the view bag approach. See the blog entry Dynamic V Strongly Typed Views for more information.

Well, that was a kind of an "M" for model, but not the database kind. Let's take what we've learned and create a database of movies.

Adding a Model

9/16/2020 • 2 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section you'll add some classes for managing movies in a database. These classes will be the "model" part of the ASP.NET MVC app.

You'll use a .NET Framework data-access technology known as the Entity Framework to define and work with these model classes. The Entity Framework (often referred to as EF) supports a development paradigm called *Code First*. Code First allows you to create model objects by writing simple classes. (These are also known as POCO classes, from "plain-old CLR objects.") You can then have the database created on the fly from your classes, which enables a very clean and rapid development workflow. If you are required to create the database first, you can still follow this tutorial to learn about MVC and EF app development. You can then follow Tom Fizmakens ASP.NET Scaffolding tutorial, which covers the database first approach.

Adding Model Classes

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Enter the *class* name "Movie".

Add the following five properties to the `Movie` class:

```
using System;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }
}
```

We'll use the `Movie` class to represent movies in a database. Each instance of a `Movie` object will correspond to a row within a database table, and each property of the `Movie` class will map to a column in the table.

Note: In order to use System.Data.Entity, and the related class, you need to install the Entity Framework NuGet Package. Follow the link for further instructions.

In the same file, add the following `MovieDBContext` class:

```
using System;
using System.Data.Entity;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

The `MovieDBContext` class represents the Entity Framework movie database context, which handles fetching, storing, and updating `Movie` class instances in a database. The `MovieDBContext` derives from the `DbContext` base class provided by the Entity Framework.

In order to be able to reference `DbContext` and `DbSet`, you need to add the following `using` statement at the top of the file:

```
using System.Data.Entity;
```

You can do this by manually adding the using statement, or you can hover over the red squiggly lines, click `Show potential fixes` and click `using System.Data.Entity;`

Note: Several unused `using` statements have been removed. Visual Studio will show unused dependencies as gray. You can remove unused dependencies by hovering over the gray dependencies, click `Show potential fixes` and click **Remove Unused Usings**.

We've finally added a model (the M in MVC). In the next section you'll work with the database connection string.

Creating a Connection String and Working with SQL Server LocalDB

9/16/2020 • 3 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

Creating a Connection String and Working with SQL Server LocalDB

The `MovieDBContext` class you created handles the task of connecting to the database and mapping `Movie` objects to database records. One question you might ask, though, is how to specify which database it will connect to. You don't actually have to specify which database to use, Entity Framework will default to using LocalDB. In this section we'll explicitly add a connection string in the *Web.config* file of the application.

SQL Server Express LocalDB

LocalDB is a lightweight version of the SQL Server Express Database Engine that starts on demand and runs in user mode. LocalDB runs in a special execution mode of SQL Server Express that enables you to work with databases as *.mdf* files. Typically, LocalDB database files are kept in the *App_Data* folder of a web project.

SQL Server Express is not recommended for use in production web applications. LocalDB in particular should not be used for production with a web application because it is not designed to work with IIS. However, a LocalDB database can be easily migrated to SQL Server or SQL Azure.

In Visual Studio 2017, LocalDB is installed by default with Visual Studio.

By default, the Entity Framework looks for a connection string named the same as the object context class (`MovieDBContext` for this project). For more information see SQL Server Connection Strings for ASP.NET Web Applications.

Open the application root *Web.config* file shown below. (Not the *Web.config* file in the *Views* folder.)

Find the `<connectionStrings>` element:

```
<?xml version="1.0" encoding="utf-8"?>
<!--
  For more information on how to configure your ASP.NET application, please visit
  https://go.microsoft.com/fwlink/?LinkId=301880
  -->
<configuration>
  <configSections>
    <!-- For more information on Entity Framework configuration, visit http://go.microsoft.com/fwlink/?LinkID=237468 --
    <section name="entityFramework" type="System.Data.Entity.Internal.ConfigFile.EntityFrameworkSection, EntityFramewor
  </configSections>
  <connectionStrings>
    <add name="DefaultConnection" connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial Catalog=aspnet-MvcMovie-
  </connectionStrings>
  <appSettings>
    <add key="webpages:Version" value="3.0.0.0" />
    <add key="webpages:Enabled" value="false" />
    <add key="ClientValidationEnabled" value="true" />
    <add key="UnobtrusiveJavaScriptEnabled" value="true" />
  </appSettings>
  <system.web>
    <authentication mode="None" />
    <compilation debug="true" targetFramework="4.6.1" />
    <httpRuntime targetFramework="4.6.1" />
  </system.web>
```

Add the following connection string to the `<connectionStrings>` element in the *Web.config* file.

```
<add name="MovieDBContext"
   connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial Catalog=aspnet-MvcMovie;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|\Movies.mdf"
   providerName="System.Data.SqlClient"
/>
```

The following example shows a portion of the *Web.config* file with the new connection string added:

```
<connectionStrings>
  <add name="DefaultConnection" connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial Catalog=aspnet-
MvcMovie-fefdc1f0-bd81-4ce9-b712-93a062e01031;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|\aspnet-MvcMovie-fefdc1f0-bd81-4ce9-b712-93a062e01031.mdf"
providerName="System.Data.SqlClient" />
  <add name="MovieDBContext" connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial Catalog=aspnet-
MvcMovie;Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\Movies.mdf"
providerName="System.Data.SqlClient" />
</connectionStrings>
```

The two connection strings are very similar. The first connection string is named `DefaultConnection` and is used for the membership database to control who can access the application. The connection string you've added specifies a LocalDB database named *Movie.mdf* located in the *App_Data* folder. We won't use the membership database in this tutorial, for more information on membership, authentication and security, see my tutorial Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure App Service.

The name of the connection string must match the name of the DbContext class.

```
using System;
using System.Data.Entity;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

You don't actually need to add the `MovieDBContext` connection string. If you don't specify a connection string, Entity Framework will create a LocalDB database in the users directory with the fully qualified name of the DbContext class (in this case `MvcMovie.Models.MovieDBContext`). You can name the database anything you like, as long as it has the *.MDF* suffix. For example, we could name the database *MyFilms.mdf*.

Next, you'll build a new `MoviesController` class that you can use to display the movie data and allow users to create new movie listings.

Accessing Your Model's Data from a Controller

9/16/2020 • 8 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section, you'll create a new `MoviesController` class and write code that retrieves the movie data and displays it in the browser using a view template.

Build the application before going on to the next step. If you don't build the application, you'll get an error adding a controller.

In Solution Explorer, right-click the *Controllers* folder and then click **Add**, then **Controller**.

In the **Add Scaffold** dialog box, click **MVC 5 Controller with views, using Entity Framework**, and then click **Add**.

- Select **Movie (MvcMovie.Models)** for the Model class.
- Select **MovieDBContext (MvcMovie.Models)** for the Data context class.
- For the Controller name enter **MoviesController**.

  The image below shows the completed dialog.

Click **Add**. (If you get an error, you probably didn't build the application before starting adding the controller.) Visual Studio creates the following files and folders:

- *A MoviesController.cs* file in the *Controllers* folder.
- A *Views\Movies* folder.
- *Create.cshtml, Delete.cshtml, Details.cshtml, Edit.cshtml*, and *Index.cshtml* in the new *Views\Movies* folder.

Visual Studio automatically created the CRUD (create, read, update, and delete) action methods and views for you (the automatic creation of CRUD action methods and views is known as scaffolding). You now have a fully functional web application that lets you create, list, edit, and delete movie entries.

Run the application and click on the **MVC Movie** link (or browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser). Because the application is relying on the default routing (defined in the *App_Start\RouteConfig.cs* file), the browser request `http://localhost:xxxxx/Movies` is routed to the default `Index` action method of the `Movies` controller. In other words, the browser request `http://localhost:xxxxx/Movies` is effectively the same as the browser request `http://localhost:xxxxx/Movies/Index`. The result is an empty list of movies, because you haven't added any yet.

Creating a Movie

Select the **Create New** link. Enter some details about a movie and then click the **Create** button.

> **NOTE**
>
> You may not be able to enter decimal points or commas in the Price field. To support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must include *globalize.js* and your specific *cultures/globalize.cultures.js* file(from https://github.com/jquery/globalize) and JavaScript to use `Globalize.parseFloat`. I'll show how to do this in the next tutorial. For now, just enter whole numbers like 10.

Clicking the **Create** button causes the form to be posted to the server, where the movie information is saved in the database. You're then redirected to the */Movies* URL, where you can see the newly created movie in the listing.

Create a couple more movie entries. Try the **Edit**, **Details**, and **Delete** links, which are all functional.

Examining the Generated Code

Open the *Controllers\MoviesController.cs* file and examine the generated `Index` method. A portion of the movie controller with the `Index` method is shown below.

```
public class MoviesController : Controller
{
    private MovieDBContext db = new MovieDBContext();

    // GET: /Movies/
    public ActionResult Index()
    {
        return View(db.Movies.ToList());
    }
```

A request to the `Movies` controller returns all the entries in the `Movies` table and then passes the results to the `Index` view. The following line from the `MoviesController` class instantiates a movie database context, as described previously. You can use the movie database context to query, edit, and delete movies.

```
private MovieDBContext db = new MovieDBContext();
```

Strongly Typed Models and the @model Keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view template using the `ViewBag` object. The `ViewBag` is a dynamic object that provides a convenient late-bound way to pass information to a view.

MVC also provides the ability to pass *strongly* typed objects to a view template. This strongly typed approach enables better compile-time checking of your code and richer IntelliSense in the Visual Studio editor. The scaffolding mechanism in Visual Studio used this approach (that is, passing a *strongly* typed model) with the `MoviesController` class and view templates when it created the methods and views.

In the *Controllers\MoviesController.cs* file examine the generated `Details` method. The `Details` method is shown below.

```
public ActionResult Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

The `id` parameter is generally passed as route data, for example `http://localhost:1234/movies/details/1` will set the controller to the movie controller, the action to `details` and the `id` to 1. You could also pass in the id with a query string as follows:

`http://localhost:1234/movies/details?id=1`

If a `Movie` is found, an instance of the `Movie` model is passed to the `Details` view:

```
return View(movie);
```

Examine the contents of the *Views\Movies\Details.cshtml* file:

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Details";
}

<h2>Details</h2>

<div>
    <h4>Movie</h4>
<hr />
    <dl class="dl-horizontal">
        <dt>
            @Html.DisplayNameFor(model => model.Title)
        </dt>
         @*Markup omitted for clarity.*@
    </dl>
</div>
<p>
    @Html.ActionLink("Edit", "Edit", new { id = Model.ID }) |
    @Html.ActionLink("Back to List", "Index")
</p>
```

By including a `@model` statement at the top of the view template file, you can specify the type of object that the view expects. When you created the movie controller, Visual Studio automatically included the following `@model` statement at the top of the *Details.cshtml* file:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows you to access the movie that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Details.cshtml* template, the code passes each movie field to the `DisplayNameFor` and DisplayFor HTML Helpers with the strongly typed `Model` object. The `Create` and `Edit` methods and view templates also pass a movie model object.

Examine the *Index.cshtml* view template and the `Index` method in the *MoviesController.cs* file. Notice how the code creates a `List` object when it calls the `View` helper method in the `Index` action method. The code then passes this `Movies` list from the `Index` action method to the view:

```
public ActionResult Index()
{
    return View(db.Movies.ToList());
}
```

When you created the movie controller, Visual Studio automatically included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

This `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* template, the code loops through the movies by doing a `foreach` statement over the strongly typed `Model` object:

```
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
         <th>
            @Html.DisplayFor(modelItem => item.Rating)
        </th>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID })  |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each `item` object in the loop is typed as `Movie`. Among other benefits, this means that you get compile-time checking of the code and full IntelliSense support in the code editor:

Working with SQL Server LocalDB

Entity Framework Code First detected that the database connection string that was provided pointed to a `Movies` database that didn't exist yet, so Code First created the database automatically. You can verify that it's been created by looking in the *App_Data* folder. If you don't see the *Movies.mdf* file, click the **Show All Files** button in the **Solution Explorer** toolbar, click the **Refresh** button, and then expand the *App_Data* folder.

Double-click *Movies.mdf* to open **SERVER EXPLORER**, then expand the **Tables** folder to see the Movies table. Note the key icon next to ID. By default, EF will make a property named ID the primary key. For more information on EF and MVC, see Tom Dykstra's excellent tutorial on MVC and EF.

Right-click the `Movies` table and select **Show Table Data** to see the data you created.

Right-click the `Movies` table and select **Open Table Definition** to see the table structure that Entity Framework Code First created for you.

Notice how the schema of the `Movies` table maps to the `Movie` class you created earlier. Entity Framework Code First automatically created this schema for you based on your `Movie` class.

When you're finished, close the connection by right clicking *MovieDBContext* and selecting **Close Connection**. (If you don't close the connection, you might get an error the next time you run the project).

You now have a database and pages to display, edit, update and delete data. In the next tutorial, we'll examine the rest of the scaffolded code and add a `SearchIndex` method and a `SearchIndex` view that lets you search for movies in this database. For more information on using Entity Framework with MVC, see Creating an Entity Framework Data Model for an ASP.NET MVC Application.

Examining the Edit Methods and Edit View

9/16/2020 • 10 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section, you'll examine the generated `Edit` action methods and views for the movie controller. But first we'll take a short diversion to make the release date look better. Open the *Models\Movie.cs* file and add the highlighted lines shown below:

```
using System;
using System.ComponentModel.DataAnnotations;
using System.Data.Entity;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }

        [Display(Name = "Release Date")]
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

You can also make the date culture specific like this:

```
[Display(Name = "Release Date")]
[DataType(DataType.Date)]
[DisplayFormat(DataFormatString = "{0:d}", ApplyFormatInEditMode = true)]
public DateTime ReleaseDate { get; set; }
```

We'll cover DataAnnotations in the next tutorial. The Display attribute specifies what to display for the name of a field (in this case "Release Date" instead of "ReleaseDate"). The DataType attribute specifies the type of the data, in this case it's a date, so the time information stored in the field is not displayed. The DisplayFormat attribute is

needed for a bug in the Chrome browser that renders date formats incorrectly.

Run the application and browse to the `Movies` controller. Hold the mouse pointer over an **Edit** link to see the URL that it links to.

The **Edit** link was generated by the `Html.ActionLink` method in the *Views\Movies\Index.cshtml* view:

```
@Html.ActionLink("Edit", "Edit", new { id=item.ID })
```

The `Html` object is a helper that's exposed using a property on the System.Web.Mvc.WebViewPage base class. The `ActionLink` method of the helper makes it easy to dynamically generate HTML hyperlinks that link to action methods on controllers. The first argument to the `ActionLink` method is the link text to render (for example, `<a>Edit Me</a>`). The second argument is the name of the action method to invoke (In this case, the `Edit` action). The final argument is an anonymous object that generates the route data (in this case, the ID of 4).

The generated link shown in the previous image is `http://localhost:1234/Movies/Edit/4`. The default route (established in *App_Start\RouteConfig.cs*) takes the URL pattern `{controller}/{action}/{id}`. Therefore, ASP.NET translates `http://localhost:1234/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `ID` equal to 4. Examine the following code from the *App_Start\RouteConfig.cs* file. The MapRoute method is used to route HTTP requests to the correct controller and action method and supply the optional ID parameter. The MapRoute method is also used by the HtmlHelpers such as `ActionLink` to generate URLs given the controller, action method and any route data.

```
public static void RegisterRoutes(RouteCollection routes)
{
    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        name: "Default",
        url: "{controller}/{action}/{id}",
        defaults: new { controller = "Home", action = "Index",
            id = UrlParameter.Optional }
    );
}
```

You can also pass action method parameters using a query string. For example, the URL `http://localhost:1234/Movies/Edit?ID=3` also passes the parameter `ID` of 3 to the `Edit` action method of the `Movies` controller.

Open the `Movies` controller. The two `Edit` action methods are shown below.

```
// GET: /Movies/Edit/5
public ActionResult Edit(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}

// POST: /Movies/Edit/5
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see https://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit([Bind(Include="ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

Notice the second `Edit` action method is preceded by the `HttpPost` attribute. This attribute specifies that the overload of the `Edit` method can be invoked only for POST requests. You could apply the `HttpGet` attribute to the first edit method, but that's not necessary because it's the default. (We'll refer to action methods that are implicitly assigned the `HttpGet` attribute as `HttpGet` methods.) The Bind attribute is another important security mechanism that keeps hackers from over-posting data to your model. You should only include properties in the bind attribute that you want to change. You can read about overposting and the bind attribute in my overposting security note. In the simple model used in this tutorial, we will be binding all the data in the model. The ValidateAntiForgeryToken attribute is used to prevent forgery of a request and is paired up with `@Html.AntiForgeryToken()` in the edit view file (*Views\Movies\Edit.cshtml*), a portion is shown below:

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Edit";
}
<h2>Edit</h2>
@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        @Html.ValidationSummary(true)
        @Html.HiddenFor(model => model.ID)

        <div class="form-group">
            @Html.LabelFor(model => model.Title, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Title)
                @Html.ValidationMessageFor(model => model.Title)
            </div>
        </div>
```

`@Html.AntiForgeryToken()` generates a hidden form anti-forgery token that must match in the `Edit` method of the `Movies` controller. You can read more about Cross-site request forgery (also known as XSRF or CSRF) in my tutorial XSRF/CSRF Prevention in MVC.

The `HttpGet` `Edit` method takes the movie ID parameter, looks up the movie using the Entity Framework `Find` method, and returns the selected movie to the Edit view. If a movie cannot be found, HttpNotFound is returned. When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated by the visual studio scaffolding system:

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Edit";
}
<h2>Edit</h2>
@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        @Html.ValidationSummary(true)
        @Html.HiddenFor(model => model.ID)

        <div class="form-group">
            @Html.LabelFor(model => model.Title, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Title)
                @Html.ValidationMessageFor(model => model.Title)
            </div>
        </div>
        <div class="form-group">
            @Html.LabelFor(model => model.ReleaseDate, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.ReleaseDate)
                @Html.ValidationMessageFor(model => model.ReleaseDate)
            </div>
        </div>
        @*Genre and Price removed for brevity.*@
        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </div>
    </div>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file — this specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several *helper methods* to streamline the HTML markup. The `Html.LabelFor` helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The `Html.EditorFor` helper renders an HTML `<input>` element. The `Html.ValidationMessageFor` helper displays any validation messages associated with that property.

Run the application and navigate to the */Movies* URL. Click an **Edit** link. In the browser, view the source for the page. The HTML for the form element is shown below.

```
<form action="/movies/Edit/4" method="post">
   <input name="__RequestVerificationToken" type="hidden" value="UxY6bkQyJCXO3Kn5AXg-
6TXxOj6yVBi9tghHaQ5Lq_qwKvcojNXEEfcbn-FGh_0vuw4tS_BRk7QQQHlJp8AP4_X4orVNoQnp2cd8kXhykS01" />  <fieldset
class="form-horizontal">
      <legend>Movie</legend>

      <input data-val="true" data-val-number="The field ID must be a number." data-val-required="The ID field
is required." id="ID" name="ID" type="hidden" value="4" />

      <div class="control-group">
         <label class="control-label" for="Title">Title</label>
         <div class="controls">
            <input class="text-box single-line" id="Title" name="Title" type="text" value="GhostBusters" />
            <span class="field-validation-valid help-inline" data-valmsg-for="Title" data-valmsg-
replace="true"></span>
         </div>
      </div>

      <div class="control-group">
         <label class="control-label" for="ReleaseDate">Release Date</label>
         <div class="controls">
            <input class="text-box single-line" data-val="true" data-val-date="The field Release Date must be
a date." data-val-required="The Release Date field is required." id="ReleaseDate" name="ReleaseDate"
type="date" value="1/1/1984" />
            <span class="field-validation-valid help-inline" data-valmsg-for="ReleaseDate" data-valmsg-
replace="true"></span>
         </div>
      </div>

      <div class="control-group">
         <label class="control-label" for="Genre">Genre</label>
         <div class="controls">
            <input class="text-box single-line" id="Genre" name="Genre" type="text" value="Comedy" />
            <span class="field-validation-valid help-inline" data-valmsg-for="Genre" data-valmsg-
replace="true"></span>
         </div>
      </div>

      <div class="control-group">
         <label class="control-label" for="Price">Price</label>
         <div class="controls">
            <input class="text-box single-line" data-val="true" data-val-number="The field Price must be a
number." data-val-required="The Price field is required." id="Price" name="Price" type="text" value="7.99" />
            <span class="field-validation-valid help-inline" data-valmsg-for="Price" data-valmsg-
replace="true"></span>
         </div>
      </div>

      <div class="form-actions no-color">
         <input type="submit" value="Save" class="btn" />
      </div>
   </fieldset>
</form>
```

The `<input>` elements are in an HTML `<form>` element whose `action` attribute is set to post to the */Movies/Edit* URL. The form data will be posted to the server when the **Save** button is clicked. The second line shows the hidden XSRF token generated by the `@Html.AntiForgeryToken()` call.

Processing the POST Request

The following listing shows the `HttpPost` version of the `Edit` action method.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit([Bind(Include="ID,Title,ReleaseDate,Genre,Price")] Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The ValidateAntiForgeryToken attribute validates the XSRF token generated by the `@Html.AntiForgeryToken()` call in the view.

The ASP.NET MVC model binder takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, the movie data is saved to the `Movies` collection of the `db` (`MovieDBContext` instance). The new movie data is saved to the database by calling the `SaveChanges` method of `MovieDBContext`. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the movie collection, including the changes just made.

As soon as the client-side validation determines the value of a field isn't valid, an error message is displayed. If JavaScript is disabled, client side validation is disabled. However, the server detects the posted values aren't valid, and the form values are redisplayed with error messages.

Validation is examined in more detail later in the tutorial.

The `Html.ValidationMessageFor` helpers in the *Edit.cshtml* view template take care of displaying appropriate error messages.

All the `HttpGet` methods follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the model to the view. The `Create` method passes an empty movie object to the Create view. All the methods that create, edit, delete, or otherwise modify data do so in the `HttpPost` overload of the method. Modifying data in an HTTP GET method is a security risk, as described in the blog post entry ASP.NET MVC Tip #46 – Don't use Delete Links because they create Security Holes. Modifying data in a GET method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests should not change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

jQuery validation for non-English locales

If you are using a US-English computer, you can skip this section and go to the next tutorial. You can download the Globalize version of this tutorial here. For an excellent two part tutorial on Internationalization, see Nadeem's ASP.NET MVC 5 Internationalization.

> **NOTE**
>
> to support jQuery validation for non-English locales that use a comma (",") for a decimal point, and non US-English date formats, you must include *globalize.js* and your specific *cultures/globalize.cultures.js* file(from https://github.com/jquery/globalize) and JavaScript to use `Globalize.parseFloat`. You can get the jQuery non-English validation from NuGet. (Don't install Globalize if you are using a English locale.)

1. From the **Tools** menu click **NuGet Package Manager**, and then click **Manage NuGet Packages for Solution**.

2. On the left pane, select **Browse***.*(See the image below.)

3. In the input box, enter *Globalize**.

Choose `jQuery.Validation.Globalize`, choose `MvcMovie` and click **Install**. The *Scripts\jquery.globalize\globalize.js* file will be added to your project. The

Scripts\jquery.globalize\cultures folder will contain many culture JavaScript files. Note, it may take five minutes to install this package.

The following code shows the modifications to the Views\Movies\Edit.cshtml file:

```
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")

<script src="~/Scripts/globalize/globalize.js"></script>
<script
src="~/Scripts/globalize/cultures/globalize.culture.@(System.Threading.Thread.CurrentThread.CurrentCulture.Nam
e).js"></script>
<script>
    $.validator.methods.number = function (value, element) {
        return this.optional(element) ||
            !isNaN(Globalize.parseFloat(value));
    }
    $(document).ready(function () {
        Globalize.culture('@(System.Threading.Thread.CurrentThread.CurrentCulture.Name)');
    });
</script>
<script>
    jQuery.extend(jQuery.validator.methods, {
        range: function (value, element, param) {
            //Use the Globalization plugin to parse the value
            var val = Globalize.parseFloat(value);
            return this.optional(element) || (
                val >= param[0] && val <= param[1]);
        }
    });
    $.validator.methods.date = function (value, element) {
        return this.optional(element) ||
            Globalize.parseDate(value) ||
            Globalize.parseDate(value, "yyyy-MM-dd");
    }
</script>
}
```

To avoid repeating this code in every Edit view, you can move it to the layout file. To optimize the script download, see my tutorial Bundling and Minification.

For more information see ASP.NET MVC 3 Internationalization and ASP.NET MVC 3 Internationalization - Part 2 (NerdDinner).

As a temporary fix, if you can't get validation working in your locale, you can force your computer to use US English or you can disable JavaScript in your browser. To force your computer to use US English, you can add the globalization element to the projects root *web.config* file. The following code shows the globalization element with the culture set to United States English.

```
<system.web>
    <globalization culture ="en-US" />
    <!--elements removed for clarity-->
  </system.web>
```

In the next tutorial, we'll implement search functionality.

PREVIOUS NEXT

Search

9/16/2020 • 9 minutes to read • Edit Online

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

Adding a Search Method and Search View

In this section you'll add search capability to the `Index` action method that lets you search movies by genre or name.

Prerequisites

To match this section's screenshots, you need to run the application (F5) and add the following movies to the database.

TITLE	RELEASE DATE	GENRE	PRICE
Ghostbusters	6/8/1984	Comedy	6.99
Ghostbusters II	6/16/1989	Comedy	6.99
Planet of the Apes	3/27/1986	Action	5.99

Updating the Index Form

Start by updating the `Index` action method to the existing `MoviesController` class. Here's the code:

```
public ActionResult Index(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

The first line of the `Index` method creates the following LINQ query to select the movies:

```
var movies = from m in db.Movies
                 select m;
```

The query is defined at this point, but hasn't yet been run against the database.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string, using the following code:

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s => s.Title.Contains(searchString));
}
```

The `s => s.Title` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method used in the above code. LINQ queries are not executed when they are defined or when they are modified by calling a method such as `Where` or `OrderBy` . Instead, query execution is deferred, which means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToList` method is called. In the `Search` sample, the query is executed in the *Index.cshtml* view. For more information about deferred query execution, see Query Execution.

> **NOTE**
> The Contains method is run on the database, not the c# code above. On the database, Contains maps to SQL LIKE, which is case insensitive.

Now you can update the `Index` view that will display the form to the user.

Run the application and navigate to */Movies/Index*. Append a query string such as `?searchString=ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `Index` method to have a parameter named `id`, the `id` parameter will match the `{id}` placeholder for the default routes set in the *App_Start\RouteConfig.cs* file.

```
{controller}/{action}/{id}
```

The original `Index` method looks like this::

```
public ActionResult Index(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

The modified `Index` method would look as follows:

```
public ActionResult Index(string id)
{
    string searchString = id;
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you'll add UI to help them filter movies. If you changed the signature of the `Index` method to test how to pass the route-bound ID parameter, change it back so that your `Index` method takes a string parameter named `searchString`:

```
public ActionResult Index(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

Open the *Views\Movies\Index.cshtml* file, and just after `@Html.ActionLink("Create New", "Create")`, add the form markup highlighted below:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>
    @Html.ActionLink("Create New", "Create")

     @using (Html.BeginForm()){
         <p> Title: @Html.TextBox("SearchString") <br />
         <input type="submit" value="Filter" /></p>
        }
</p>
```

The `Html.BeginForm` helper creates an opening `<form>` tag. The `Html.BeginForm` helper causes the form to post to itself when the user submits the form by clicking the **Filter** button.

Visual Studio 2013 has a nice improvement when displaying and editing View files. When you run the application with a view file open, Visual Studio 2013 invokes the correct controller action method to display the view.

With the Index view open in Visual Studio (as shown in the image above), tap Ctr F5 or F5 to run the application and then try searching for a movie.

There's no `HttpPost` overload of the `Index` method. You don't need it, because the method isn't changing the state of the application, just filtering data.

You could add the following `HttpPost Index` method. In that case, the action invoker would match the `HttpPost Index` method, and the `HttpPost Index` method would run as shown in the image below.

```
[HttpPost]
public string Index(FormCollection fc, string searchString)
{
    return "<h3> From [HttpPost]Index: " + searchString + "</h3>";
}
```

From [HttpPost]Index: ghost

However, even if you add this `HttpPost` version of the `Index` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:xxxxx/Movies/Index) -- there's no search information in the URL itself. Right now, the search string information is sent to the server as a form field value. This means you can't capture that search information to bookmark or send to friends in a URL.

The solution is to use an overload of `BeginForm` that specifies that the POST request should add the search information to the URL and that it should be routed to the `HttpGet` version of the `Index` method. Replace the existing parameterless `BeginForm` method with the following markup:

```
@using (Html.BeginForm("Index","Movies",FormMethod.Get))
```

Now when you submit a search, the URL contains a search query string. Searching will also go to the

`HttpGet Index` action method, even if you have a `HttpPost Index` method.

Adding Search by Genre

If you added the `HttpPost` version of the `Index` method, delete it now.

Next, you'll add a feature to let users search for movies by genre. Replace the `Index` method with the following code:

```
public ActionResult Index(string movieGenre, string searchString)
{
    var GenreLst = new List<string>();

    var GenreQry = from d in db.Movies
                   orderby d.Genre
                   select d.Genre;

    GenreLst.AddRange(GenreQry.Distinct());
    ViewBag.movieGenre = new SelectList(GenreLst);

    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    return View(movies);
}
```

This version of the `Index` method takes an additional parameter, namely `movieGenre`. The first few lines of code create a `List` object to hold movie genres from the database.

The following code is a LINQ query that retrieves all the genres from the database.

```
var GenreQry = from d in db.Movies
               orderby d.Genre
               select d.Genre;
```

The code uses the `AddRange` method of the generic `List` collection to add all the distinct genres to the list.

(Without the `Distinct` modifier, duplicate genres would be added — for example, comedy would be added twice in our sample). The code then stores the list of genres in the `ViewBag.MovieGenre` object. Storing category data (such a movie genres) as a SelectList object in a `ViewBag`, then accessing the category data in a dropdown list box is a typical approach for MVC applications.

The following code shows how to check the `movieGenre` parameter. If it's not empty, the code further constrains the movies query to limit the selected movies to the specified genre.

```
if (!string.IsNullOrEmpty(movieGenre))
{
    movies = movies.Where(x => x.Genre == movieGenre);
}
```

As stated previously, the query is not run on the database until the movie list is iterated over (which happens in the View, after the `Index` action method returns).

Adding Markup to the Index View to Support Search by Genre

Add an `Html.DropDownList` helper to the *Views\Movies\Index.cshtml* file, just before the `TextBox` helper. The completed markup is shown below:

```
@model IEnumerable<MvcMovie.Models.Movie>
@{
    ViewBag.Title = "Index";
}
<h2>Index</h2>
<p>
    @Html.ActionLink("Create New", "Create")
    @using (Html.BeginForm("Index", "Movies", FormMethod.Get))
    {
    <p>
        Genre: @Html.DropDownList("movieGenre", "All")
        Title: @Html.TextBox("SearchString")
        <input type="submit" value="Filter" />
    </p>
    }
</p>
<table class="table">
```

In the following code:

```
@Html.DropDownList("movieGenre", "All")
```

The parameter "MovieGenre" provides the key for the `DropDownList` helper to find a `IEnumerable<SelectListItem>` in the `ViewBag`. The `ViewBag` was populated in the action method:

```
public ActionResult Index(string movieGenre, string searchString)
{
    var GenreLst = new List<string>();

    var GenreQry = from d in db.Movies
                   orderby d.Genre
                   select d.Genre;

    GenreLst.AddRange(GenreQry.Distinct());
    ViewBag.movieGenre = new SelectList(GenreLst);

    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (!string.IsNullOrEmpty(movieGenre))
    {
        movies = movies.Where(x => x.Genre == movieGenre);
    }

    return View(movies);
}
```

The parameter "All" provides an option label. If you inspect that choice in your browser, you'll see that its "value" attribute is empty. Since our controller only filters `if` the string is not `null` or empty, submitting an empty value for `movieGenre` shows all genres.

You can also set an option to be selected by default. If you wanted "Comedy" as your default option, you would change the code in the Controller like so:

```
ViewBag.movieGenre = new SelectList(GenreLst, "Comedy");
```

Run the application and browse to */Movies/Index*. Try a search by genre, by movie name, and by both criteria.

In this section you created a search action method and view that let users search by movie title and genre. In the next section, you'll look at how to add a property to the `Movie` model and how to add an initializer that will automatically create a test database.

Adding a New Field

9/16/2020 • 11 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section you'll use Entity Framework Code First Migrations to migrate some changes to the model classes so the change is applied to the database.

By default, when you use Entity Framework Code First to automatically create a database, as you did earlier in this tutorial, Code First adds a table to the database to help track whether the schema of the database is in sync with the model classes it was generated from. If they aren't in sync, the Entity Framework throws an error. This makes it easier to track down issues at development time that you might otherwise only find (by obscure errors) at run time.

Setting up Code First Migrations for Model Changes

Navigate to Solution Explorer. Right click on the *Movies.mdf* file and select **Delete** to remove the movies database. If you don't see the *Movies.mdf* file, click on the **Show All Files** icon shown below in the red outline.

Build the application to make sure there are no errors.

From the **Tools** menu, click **NuGet Package Manager** and then **Package Manager Console**.

In the **Package Manager Console** window at the `PM>` prompt enter

Enable-Migrations -ContextTypeName MvcMovie.Models.MovieDBContext

The **Enable-Migrations** command (shown above) creates a *Configuration.cs* file in a new *Migrations* folder.

Visual Studio opens the *Configuration.cs* file. Replace the `Seed` method in the *Configuration.cs* file with the following code:

```
protected override void Seed(MvcMovie.Models.MovieDBContext context)
{
    context.Movies.AddOrUpdate( i => i.Title,
        new Movie
        {
            Title = "When Harry Met Sally",
            ReleaseDate = DateTime.Parse("1989-1-11"),
            Genre = "Romantic Comedy",
            Price = 7.99M
        },

         new Movie
         {
             Title = "Ghostbusters ",
             ReleaseDate = DateTime.Parse("1984-3-13"),
             Genre = "Comedy",
             Price = 8.99M
         },

         new Movie
         {
             Title = "Ghostbusters 2",
             ReleaseDate = DateTime.Parse("1986-2-23"),
             Genre = "Comedy",
             Price = 9.99M
         },

        new Movie
        {
            Title = "Rio Bravo",
            ReleaseDate = DateTime.Parse("1959-4-15"),
            Genre = "Western",
            Price = 3.99M
        }
    );

}
```

Hover over the red squiggly line under `Movie` and click `Show Potential Fixes` and then click **using MvcMovie.Models;**

Doing so adds the following using statement:

```
using MvcMovie.Models;
```

NOTE

Code First Migrations calls the `Seed` method after every migration (that is, calling **update-database** in the Package Manager Console), and this method updates rows that have already been inserted, or inserts them if they don't exist yet.

The AddOrUpdate method in the following code performs an "upsert" operation:

```
context.Movies.AddOrUpdate(i => i.Title,
    new Movie
    {
        Title = "When Harry Met Sally",
        ReleaseDate = DateTime.Parse("1989-1-11"),
        Genre = "Romantic Comedy",
        Rating = "PG",
        Price = 7.99M
    }
```

Because the Seed method runs with every migration, you can't just insert data, because the rows you are trying to add will already be there after the first migration that creates the database. The "upsert" operation prevents errors that would happen if you try to insert a row that already exists, but it overrides any changes to data that you may have made while testing the application. With test data in some tables you might not want that to happen: in some cases when you change data while testing you want your changes to remain after database updates. In that case you want to do a conditional insert operation: insert a row only if it doesn't already exist.

The first parameter passed to the AddOrUpdate method specifies the property to use to check if a row already exists. For the test movie data that you are providing, the `Title` property can be used for this purpose since each title in the list is unique:

```
context.Movies.AddOrUpdate(i => i.Title,
```

This code assumes that titles are unique. If you manually add a duplicate title, you'll get the following exception the next time you perform a migration.

Sequence contains more than one element

For more information about the AddOrUpdate method, see Take care with EF 4.3 AddOrUpdate Method..

Press CTRL-SHIFT-B to build the project.(The following steps will fail if you don't build at this point.)

The next step is to create a `DbMigration` class for the initial migration. This migration creates a new database, that's why you deleted the *movie.mdf* file in a previous step.

In the **Package Manager Console** window, enter the command `add-migration Initial` to create the initial migration. The name "Initial" is arbitrary and is used to name the migration file created.

Code First Migrations creates another class file in the *Migrations* folder (with the name *{DateStamp}_Initial.cs*), and this class contains code that creates the database schema. The migration filename is pre-fixed with a timestamp to help with ordering. Examine the *{DateStamp}_Initial.cs* file, it contains the instructions to create the `Movies` table for the Movie DB. When you update the database in the instructions below, this *{DateStamp}_Initial.cs* file will run and create the DB schema. Then the **Seed** method will run to populate the DB with test data.

In the **Package Manager Console**, enter the command `update-database` to create the database and run the

`Seed` method.

If you get an error that indicates a table already exists and can't be created, it is probably because you ran the application after you deleted the database and before you executed `update-database`. In that case, delete the *Movies.mdf* file again and retry the `update-database` command. If you still get an error, delete the migrations folder and contents then start with the instructions at the top of this page (that is delete the *Movies.mdf* file then proceed to Enable-Migrations). If you still get an error, open SQL Server Object Explorer and remove the database from the list.

Run the application and navigate to the */Movies* URL. The seed data is displayed.

Adding a Rating Property to the Movie Model

Start by adding a new `Rating` property to the existing `Movie` class. Open the *Models\Movie.cs* file and add the `Rating` property like this one:

```
public string Rating { get; set; }
```

The complete `Movie` class now looks like the following code:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the application (Ctrl+Shift+B).

Because you've added a new field to the `Movie` class, you also need to update the binding *white list* so this new property will be included. Update the `bind` attribute for `Create` and `Edit` action methods to include the `Rating` property:

```
[Bind(Include = "ID,Title,ReleaseDate,Genre,Price,Rating")]
```

You also need to update the view templates in order to display, create and edit the new `Rating` property in the browser view.

Open the *\Views\Movies\Index.cshtml* file and add a `<th>Rating</th>` column heading just after the **Price** column. Then add a `<td>` column near the end of the template to render the `@item.Rating` value. Below is what the updated *Index.cshtml* view template looks like:

```
@model IEnumerable<MvcMovie.Models.Movie>
@{
    ViewBag.Title = "Index";
}
<h2>Index</h2>
<p>
    @Html.ActionLink("Create New", "Create")
    @using (Html.BeginForm("Index", "Movies", FormMethod.Get))
    {
    <p>
        Genre: @Html.DropDownList("movieGenre", "All")
        Title: @Html.TextBox("SearchString")
        <input type="submit" value="Filter" />
    </p>
    }
</p>
<table class="table">
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Title)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Genre)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Price)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Rating)
        </th>

        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Rating)
        </td>

        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}

</table>
```

Next, open the *\Views\Movies\Create.cshtml* file and add the `Rating` field with the following highlighted markup.

This renders a text box so that you can specify a rating when a new movie is created.

```
<div class="form-group">
            @Html.LabelFor(model => model.Price, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Price, new { htmlAttributes = new { @class = "form-control" }
})
                @Html.ValidationMessageFor(model => model.Price, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Rating, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Rating, new { htmlAttributes = new { @class = "form-control" }
})
                @Html.ValidationMessageFor(model => model.Rating, "", new { @class = "text-danger" })
            </div>
        </div>

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </div>
    </div>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

You've now updated the application code to support the new `Rating` property.

Run the application and navigate to the */Movies* URL. When you do this, though, you'll see one of the following errors:

The model backing the 'MovieDBContext' context has changed since the database was created. Consider using Code First Migrations to update the database (https://go.microsoft.com/fwlink/?LinkId=238269).

You're seeing this error because the updated `Movie` model class in the application is now different than the schema of the `Movie` table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient early in the development cycle when you are doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you *don't* want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develop an application. For more information on Entity Framework database initializers, see ASP.NET MVC/Entity Framework tutorial.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, we'll use Code First Migrations.

Update the Seed method so that it provides a value for the new column. Open Migrations\Configuration.cs file and add a Rating field to each Movie object.

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "PG",
    Price = 7.99M
},
```

Build the solution, and then open the **Package Manager Console** window and enter the following command:

```
add-migration Rating
```

The `add-migration` command tells the migration framework to examine the current movie model with the current movie DB schema and create the necessary code to migrate the DB to the new model. The name *Rating* is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration step.

When this command finishes, Visual Studio opens the class file that defines the new `DbMigration` derived class, and in the `Up` method you can see the code that creates the new column.

```
public partial class AddRatingMig : DbMigration
{
    public override void Up()
    {
        AddColumn("dbo.Movies", "Rating", c => c.String());
    }

    public override void Down()
    {
        DropColumn("dbo.Movies", "Rating");
    }
}
```

Build the solution, and then enter the `update-database` command in the **Package Manager Console** window.

The following image shows the output in the **Package Manager Console** window (The date stamp prepending *Rating* will be different.)

```
PM> update-database
Specify the '-Verbose' flag to view the SQL statements being applied to the target database.
Applying explicit migrations: [201711171332278_Rating].
Applying explicit migration: 201711171332278_Rating.
Running Seed method.
PM>
```

Re-run the application and navigate to the /Movies URL. You can see the new Rating field.

Click the **Create New** link to add a new movie. Note that you can add a rating.

Click **Create**. The new movie, including the rating, now shows up in the movies listing:

Now that the project is using migrations, you won't need to drop the database when you add a new field or otherwise update the schema. In the next section, we'll make more schema changes and use migrations to update the database.

You should also add the `Rating` field to the Edit, Details, and Delete view templates.

You could enter the "update-database" command in the **Package Manager Console** window again and no migration code would run, because the schema matches the model. However, running "update-database" will run the `Seed` method again, and if you changed any of the Seed data, the changes will be lost because the `Seed` method upserts data. You can read more about the `Seed` method in Tom Dykstra's popular ASP.NET MVC/Entity Framework tutorial.

In this section you saw how you can modify model objects and keep the database in sync with the changes. You also learned a way to populate a newly created database with sample data so you can try out scenarios. This was

just a quick introduction to Code First, see Creating an Entity Framework Data Model for an ASP.NET MVC Application for a more complete tutorial on the subject. Next, let's look at how you can add richer validation logic to the model classes and enable some business rules to be enforced.

PREVIOUS NEXT

Adding Validation

9/16/2020 • 13 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this section you'll add validation logic to the `Movie` model, and you'll ensure that the validation rules are enforced any time a user attempts to create or edit a movie using the application.

Keeping Things DRY

One of the core design tenets of ASP.NET MVC is DRY ("Don't Repeat Yourself"). ASP.NET MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an application. This reduces the amount of code you need to write and makes the code you do write less error prone and easier to maintain.

The validation support provided by ASP.NET MVC and Entity Framework Code First is a great example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the application.

Let's look at how you can take advantage of this validation support in the movie application.

Adding Validation Rules to the Movie Model

You'll begin by adding some validation logic to the `Movie` class.

Open the *Movie.cs* file. Notice the `System.ComponentModel.DataAnnotations` namespace does not contain `System.Web`. DataAnnotations provides a built-in set of validation attributes that you can apply declaratively to any class or property. (It also contains formatting attributes like DataType that help with formatting and don't provide any validation.)

Now update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, RegularExpression, and `Range` validation attributes. Replace the `Movie` class with the following:

```
public class Movie
{
    public int ID { get; set; }

    [StringLength(60, MinimumLength = 3)]
    public string Title { get; set; }

    [Display(Name = "Release Date")]
    [DataType(DataType.Date)]
    [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
    public DateTime ReleaseDate { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z'\s]*$")]
    [Required]
    [StringLength(30)]
    public string Genre { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    public decimal Price { get; set; }

    [RegularExpression(@"^[A-Z]+[a-zA-Z'\s]*$")]
    [StringLength(5)]
    public string Rating { get; set; }
}
```

The `StringLength` attribute sets the maximum length of the string, and it sets this limitation on the database, therefore the database schema will change. Right click on the **Movies** table in **Server explorer** and click **Open Table Definition**:

In the image above, you can see all the string fields are set to NVARCHAR (MAX). We will use migrations to update the schema. Build the solution, and then open the **Package Manager Console** window and enter the following commands:

```
add-migration DataAnnotations
update-database
```

When this command finishes, Visual Studio opens the class file that defines the new `DbMigration` derived class with the name specified (`DataAnnotations`), and in the `Up` method you can see the code that updates the schema constraints:

```
public override void Up()
{
    AlterColumn("dbo.Movies", "Title", c => c.String(maxLength: 60));
    AlterColumn("dbo.Movies", "Genre", c => c.String(nullable: false, maxLength: 30));
    AlterColumn("dbo.Movies", "Rating", c => c.String(maxLength: 5));
}
```

The `Genre` field is no longer nullable (that is, you must enter a value). The `Rating` field has a maximum length of 5 and `Title` has a maximum length of 60. The minimum length of 3 on `Title` and the range on `Price` did not create schema changes.

Examine the Movie schema:

The string fields show the new length limits and `Genre` is no longer checked as nullable.

The validation attributes specify behavior that you want to enforce on the model properties they are applied to. The `Required` and `MinimumLength` attributes indicates that a property must have a value; but nothing prevents a user from entering white space to satisfy this validation. The RegularExpression attribute is used to limit what characters can be input. In the code above, `Genre` and `Rating` must use only letters (white space, numbers and special characters are not allowed). The `Range` attribute constrains a value to within a specified range. The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length. Value types (such as `decimal, int, float, DateTime`) are inherently required and don't need the `Required` attribute.

Code First ensures that the validation rules you specify on a model class are enforced before the application saves changes in the database. For example, the code below will throw a DbEntityValidationException exception when the `SaveChanges` method is called, because several required `Movie` property values are missing:

```
MovieDBContext db = new MovieDBContext();
Movie movie = new Movie();
movie.Title = "Gone with the Wind";
db.Movies.Add(movie);
db.SaveChanges();        // <= Will throw server side validation exception
```

The code above throws the following exception:

Validation failed for one or more entities. See 'EntityValidationErrors' property for more details.

Having validation rules automatically enforced by the .NET Framework helps make your application more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Validation Error UI in ASP.NET MVC

Run the application and navigate to the */Movies* URL.

Click the **Create New** link to add a new movie. Fill out the form with some invalid values. As soon as jQuery client side validation detects the error, it displays an error message.

> **NOTE**
> to support jQuery validation for non-English locales that use a comma (",") for a decimal point, you must include the NuGet globalize as described previously in this tutorial.

Notice how the form has automatically used a red border color to highlight the text boxes that contain invalid data and has emitted an appropriate validation error message next to each one. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

A real benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.cshtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class. Test validation using the `Edit` action method, and the same validation is applied.

The form data is not sent to the server until there are no client side validation errors. You can verify this by putting a break point in the HTTP Post method, by using the fiddler tool, or the IE F12 developer tools.

How Validation Occurs in the Create View and Create Action Method

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The next listing shows what the `Create` methods in the `MovieController` class look like. They're unchanged from how you created them earlier in this tutorial.

```
public ActionResult Create()
{
    return View();
}
// POST: /Movies/Create
// To protect from overposting attacks, please enable the specific properties you want to bind to, for
// more details see https://go.microsoft.com/fwlink/?LinkId=317598.
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create([Bind(Include = "ID,Title,ReleaseDate,Genre,Price,Rating")] Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Movies.Add(movie);
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (the `HttpPost` version) checks `ModelState.IsValid` to see whether the movie has any validation errors. Getting this property evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method redisplays the form. If there are no errors, the method saves the new movie in the database. In our movie example, **the form isn't posted to the server when there are validation errors detected on the client side; the second `Create` method is never called**. If you disable JavaScript in your browser, client validation is disabled, and the HTTP POST `Create` method gets `ModelState.IsValid` to check whether the movie has any validation errors.

You can set a break point in the `HttpPost Create` method and verify the method is never called, client side validation will not submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript. The following image shows how to disable JavaScript in Internet Explorer.

The following image shows how to disable JavaScript in the FireFox browser.

The following image shows how to disable JavaScript in the Chrome browser.

Below is the *Create.cshtml* view template that you scaffolded earlier in the tutorial. It's used by the action methods shown above both to display the initial form and to redisplay it in the event of an error.

```
@model MvcMovie.Models.Movie
@{
    ViewBag.Title = "Create";
}
<h2>Create</h2>
@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()
    <div class="form-horizontal">
        <h4>Movie</h4>
        <hr />
        @Html.ValidationSummary(true)
        <div class="form-group">
            @Html.LabelFor(model => model.Title, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Title)
                @Html.ValidationMessageFor(model => model.Title)
            </div>
        </div>
        @*Fields removed for brevity.*@

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </div>
    </div>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

Notice how the code uses an `Html.EditorFor` helper to output the `<input>` element for each `Movie` property. Next to this helper is a call to the `Html.ValidationMessageFor` helper method. These two helper methods work with the model object that's passed by the controller to the view (in this case, a `Movie` object). They automatically look for validation attributes specified on the model and display error messages as appropriate.

What's really nice about this approach is that neither the controller nor the `Create` view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the `Edit` view and any other views templates you might create that edit your model.

If you want to change the validation logic later, you can do so in exactly one place by adding validation attributes to the model (in this example, the `movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the *DRY* principle.

Using DataType Attributes

Open the *Movie.cs* file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DataType` attribute.

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The DataType attributes only provide hints for the view engine to format the data (and supply attributes such as `<a>` for URL's and `<a href="mailto:EmailAddress.com">` for email. You can use the RegularExpression attribute to validate the format of the data. The DataType attribute is used to specify a data type that is more specific than the database intrinsic type, they are ***not*** validation attributes. In this case we only want to keep track of the date, not the date and time. The DataType Enumeration provides for many data types, such as *Date, Time, PhoneNumber, Currency, EmailAddress* and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for DataType.EmailAddress, and a date selector can be provided for DataType.Date in browsers that support HTML5. The DataType attributes emits HTML 5 data- (pronounced *data dash*) attributes that HTML 5 browsers can understand. The DataType attributes do not provide any validation.

`DataType.Date` does not specify the format of the date that is displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime EnrollmentDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the specified formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields — for example, for currency values, you might not want the currency symbol in the text box for editing.)

You can use the DisplayFormat attribute by itself, but it's generally a good idea to use the DataType attribute also. The `DataType` attribute conveys the *semantics* of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.).
- By default, the browser will render data using the correct format based on your locale.
- The DataType attribute can enable MVC to choose the right field template to render the data (the DisplayFormat if used by itself uses the string template). For more information, see Brad Wilson's ASP.NET MVC 2 Templates. (Though written for MVC 2, this article still applies to the current version of ASP.NET MVC.)

If you use the `DataType` attribute with a date field, you have to specify the `DisplayFormat` attribute also in order to ensure that the field renders correctly in Chrome browsers. For more information, see this StackOverflow thread.

NOTE

jQuery validation does not work with the Range attribute and DateTime. For example, the following code will always display a client side validation error, even when the date is in the specified range:

```
[Range(typeof(DateTime), "1/1/1966", "1/1/2020")]
```

You will need to disable jQuery date validation to use the Range attribute with DateTime. It's generally not a good practice to compile hard dates in your models, so using the Range attribute and DateTime is discouraged.

The following code shows combining attributes on one line:

```
public class Movie
{
   public int ID { get; set; }
   [Required,StringLength(60, MinimumLength = 3)]
   public string Title { get; set; }
   [Display(Name = "Release Date"),DataType(DataType.Date)]
   public DateTime ReleaseDate { get; set; }
   [Required]
   public string Genre { get; set; }
   [Range(1, 100),DataType(DataType.Currency)]
   public decimal Price { get; set; }
   [Required,StringLength(5)]
   public string Rating { get; set; }
}
```

In the next part of the series, we'll review the application and make some improvements to the automatically generated `Details` and `Delete` methods.

PREVIOUS NEXT

Examining the Details and Delete Methods

9/16/2020 • 4 minutes to read • Edit Online

by Rick Anderson

An updated version of this tutorial is available here using the latest version of Visual Studio. The new tutorial uses ASP.NET Core MVC, which provides **many** improvements over this tutorial.

This tutorial teaches ASP.NET Core MVC with controllers and views. Razor Pages is a new alternative in ASP.NET Core 2.0, a page-based programming model that makes building web UI easier and more productive. We recommend you try the Razor Pages tutorial before the MVC version. The Razor Pages tutorial:

- Is easier to follow.
- Covers more features.
- Is the preferred approach for new application development.

In this part of the tutorial, you'll examine the automatically generated `Details` and `Delete` methods.

Examining the Details and Delete Methods

Open the `Movie` controller and examine the `Details` method.

```
public ActionResult Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing a HTTP request that invokes the method. In this case it's a `GET` request with three URL segments, the `Movies` controller, the `Details` method and a `ID` value.

Code First makes it easy to search for data using the `Find` method. An important security feature built into the

method is that the code verifies that the `Find` method has found a movie before the code tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:xxxx/Movies/Details/1` to something like `http://localhost:xxxx/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you did not check for a null movie, a null movie would result in a database error.

Examine the `Delete` and `DeleteConfirmed` methods.

```
// GET: /Movies/Delete/5
public ActionResult Delete(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}

// POST: /Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public ActionResult DeleteConfirmed(int id)
{
    Movie movie = db.Movies.Find(id);
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Note that the HTTP GET `Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (`HttpPost`) the deletion. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole. For more information about this, see Stephen Walther's blog entry ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes.

The `HttpPost` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

```
// GET: /Movies/Delete/5
public ActionResult Delete(int? id)

//
// POST: /Movies/Delete/5
[HttpPost, ActionName("Delete")]
public ActionResult DeleteConfirmed(int id)
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two Delete methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

To sort this out, you can do a couple of things. One is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to

find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. This effectively performs mapping for the routing system so that a URL that includes */Delete/* for a POST request will find the `DeleteConfirmed` method.

Another common way to avoid a problem with methods that have identical names and signatures is to artificially change the signature of the POST method to include an unused parameter. For example, some developers add a parameter type `FormCollection` that is passed to the POST method, and then simply don't use the parameter:

```
public ActionResult Delete(FormCollection fcNotUsed, int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Summary

You now have a complete ASP.NET MVC application that stores data in a local DB database. You can create, read, update, delete, and search for movies.

Next Steps

After you have built and tested a web application, the next step is to make it available to other people to use over the Internet. To do that, you have to deploy it to a web hosting provider. Microsoft offers free web hosting for up to 10 web sites in a free Azure trial account. I suggest you next follow my tutorial Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL Database to Azure. An excellent tutorial is Tom Dykstra's intermediate-level Creating an Entity Framework Data Model for an ASP.NET MVC Application. Stackoverflow and the ASP.NET MVC forums are a great places to ask questions. Follow me on twitter so you can get updates on my latest tutorials.

Feedback is welcome.

Getting Started with Entity Framework 6 Code First using MVC 5

2/20/2020 • 2 minutes to read • Edit Online

The basics of using Entity Framework 6 to display and edit data in an ASP.NET MVC 5 application.

- Creating an Entity Framework Data Model
- Implementing Basic CRUD Functionality
- Sorting, Filtering, and Paging
- Connection Resiliency and Command Interception
- Code First Migrations and Deployment
- Creating a More Complex Data Model
- Reading Related Data
- Updating Related Data
- Async and Stored Procedures
- Handling Concurrency
- Implementing Inheritance
- Advanced Entity Framework Scenarios

Tutorial: Get Started with Entity Framework 6 Code First using MVC 5

2/20/2020 • 19 minutes to read • Edit Online

NOTE

For new development, we recommend ASP.NET Core Razor Pages over ASP.NET MVC controllers and views. For a tutorial series similar to this one using Razor Pages, see Tutorial: Get started with Razor Pages in ASP.NET Core. The new tutorial:

- Is easier to follow.
- Provides more EF Core best practices.
- Uses more efficient queries.
- Is more current with the latest API.
- Covers more features.
- Is the preferred approach for new application development.

In this series of tutorials, you learn how to build an ASP.NET MVC 5 application that uses Entity Framework 6 for data access. This tutorial uses the Code First workflow. For information about how to choose between Code First, Database First, and Model First, see Create a model.

This tutorial series explains how to build the Contoso University sample application. The sample application is a simple university website. With it, you can view and update student, course, and instructor information. Here are two of the screens you create:

Index - Contoso University
localhost:60569/Student
Contoso University
Index
Create New
LastName
FirstMidName
EnrollmentDate
Alexander Carson 9/1/2005 12:00:00 AM Edit | Details | Delete
Alonso Meredith 9/1/2002 12:00:00 AM Edit | Details | Delete

© 2019 - Contoso University

In this tutorial, you:

- Create an MVC web app
- Set up the site style
- Install Entity Framework 6
- Create the data model
- Create the database context
- Initialize DB with test data
- Set up EF 6 to use LocalDB
- Create controller and views
- View the database

Prerequisites

- Visual Studio 2017

Create an MVC web app

1. Open Visual Studio and create a C# web project using the **ASP.NET Web Application (.NET Framework)** template. Name the project *ContosoUniversity* and select **OK**.

2. In **New ASP.NET Web Application - ContosoUniversity**, select **MVC**.

> **NOTE**
>
> By default, the **Authentication** option is set to **No Authentication**. For this tutorial, the web app doesn't require users to sign in. Also, it doesn't restrict access based on who's signed in.

3. Select **OK** to create the project.

Set up the site style

A few simple changes will set up the site menu, layout, and home page.

1. Open *Views\Shared_Layout.cshtml*, and make the following changes:

   - Change each occurrence of "My ASP.NET Application" and "Application name" to "Contoso University".
   - Add menu entries for Students, Courses, Instructors, and Departments, and delete the Contact entry.

   The changes are highlighted in the following code snippet:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - Contoso University</title>
    @Styles.Render("~/Content/css")
    @Scripts.Render("~/bundles/modernizr")
</head>
<body>
    <div class="navbar navbar-inverse navbar-fixed-top">
        <div class="navbar-inner">
            <div class="container">
                <button type="button" class="btn btn-navbar" data-toggle="collapse" data-
target=".nav-collapse">
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                @Html.ActionLink("Contoso University", "Index", "Home", new { area = "" }, new {
@class = "navbar-brand" })
                <div class="nav-collapse collapse">
                    <ul class="nav">
                        <li>@Html.ActionLink("Home", "Index", "Home")</li>
                        <li>@Html.ActionLink("About", "About", "Home")</li>
                        <li>@Html.ActionLink("Students", "Index", "Student")</li>
                        <li>@Html.ActionLink("Courses", "Index", "Course")</li>
                        <li>@Html.ActionLink("Instructors", "Index", "Instructor")</li>
                        <li>@Html.ActionLink("Departments", "Index", "Department")</li>
                    </ul>
                </div>
            </div>
        </div>
    </div>

    <div class="container">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; @DateTime.Now.Year - Contoso University</p>
        </footer>
    </div>

    @Scripts.Render("~/bundles/jquery")
    @Scripts.Render("~/bundles/bootstrap")
    @RenderSection("scripts", required: false)
</body>
</html>
```

2. In *Views\Home\Index.cshtml*, replace the contents of the file with the following code to replace the text about ASP.NET and MVC with text about this application:

```
@{
    ViewBag.Title = "Home Page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>Contoso University is a sample application that
        demonstrates how to use Entity Framework 6 in an
        ASP.NET MVC 5 web application.</p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in the tutorial series on the
ASP.NET site.</p>
        <p><a class="btn btn-default" href="http://www.asp.net/mvc/tutorials/getting-started-with-
ef-using-mvc/">See the tutorial &raquo;</a></p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project.</p>
        <p><a class="btn btn-default"
href="https://webpifeed.blob.core.windows.net/webpifeed/Partners/ASP.NET%20MVC%20Application%20Usin
g%20Entity%20Framework%20Code%20First.zip">Download &raquo;</a></p>
    </div>
</div>
```

3. Press Ctrl+F5 to run the web site. You see the home page with the main menu.

Install Entity Framework 6

1. From the **Tools** menu, choose **NuGet Package Manager**, and then choose **Package Manager Console**.

2. In the **Package Manager Console** window, enter the following command:

```
Install-Package EntityFramework
```

This step is one of a few steps that this tutorial has you do manually, but that could have been done automatically by the ASP.NET MVC scaffolding feature. You're doing them manually so that you can see the steps required to use Entity Framework (EF). You'll use scaffolding later to create the MVC controller and views. An alternative is to let scaffolding automatically install the EF NuGet package, create the database context class, and create the connection string. When you're ready to do it that way, all you have to do is skip those steps and scaffold your MVC controller after you create your entity classes.

Create the data model

Next you'll create entity classes for the Contoso University application. You'll start with the following three entities:

Course <-> **Enrollment** <-> **Student**

ENTITIES	RELATIONSHIP
Course to Enrollment	One-to-many

ENTITIES	RELATIONSHIP
Student to Enrollment	One-to-many

There's a one-to-many relationship between `Student` and `Enrollment` entities, and there's a one-to-many relationship between `Course` and `Enrollment` entities. In other words, a student can be enrolled in any number of courses, and a course can have any number of students enrolled in it.

In the following sections, you'll create a class for each one of these entities.

> **NOTE**
> If you try to compile the project before you finish creating all of these entity classes, you'll get compiler errors.

The Student entity

- In the *Models* folder, create a class file named *Student.cs* by right-clicking on the folder in **Solution Explorer** and choosing **Add** > **Class**. Replace the template code with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property will become the primary key column of the database table that corresponds to this class. By default, Entity Framework interprets a property that's named `ID` or *classname* `ID` as the primary key.

The `Enrollments` property is a *navigation property*. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity will hold all of the `Enrollment` entities that are related to that `Student` entity. In other words, if a given `Student` row in the database has two related `Enrollment` rows (rows that contain that student's primary key value in their `StudentID` foreign key column), that `Student` entity's `Enrollments` navigation property will contain those two `Enrollment` entities.

Navigation properties are typically defined as `virtual` so that they can take advantage of certain Entity Framework functionality such as *lazy loading*. (Lazy loading will be explained later, in the Reading Related Data tutorial later in this series.)

If a navigation property can hold multiple entities (as in many-to-many or one-to-many relationships), its type must be a list in which entries can be added, deleted, and updated, such as `ICollection`.

The Enrollment entity

- In the *Models* folder, create *Enrollment.cs* and replace the existing code with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public virtual Course Course { get; set; }
        public virtual Student Student { get; set; }
    }
}
```

The `EnrollmentID` property will be the primary key; this entity uses the *classname* `ID` pattern instead of `ID` by itself as you saw in the `Student` entity. Ordinarily you would choose one pattern and use it throughout your data model. Here, the variation illustrates that you can use either pattern. In a later tutorial, you'll see how using `ID` without `classname` makes it easier to implement inheritance in the data model.

The `Grade` property is an enum. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade — null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity (unlike the `Student.Enrollments` navigation property you saw earlier, which can hold multiple `Enrollment` entities).

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

Entity Framework interprets a property as a foreign key property if it's named *<navigation property name>* *<primary key property name>* (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named the same simply *<primary key property name>* (for example, `CourseID` since the `Course` entity's primary key is `CourseID`).

The Course entity

- In the *Models* folder, create *Course.cs*, replacing the template code with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

We'll say more about the DatabaseGeneratedAttribute attribute in a later tutorial in this series. Basically, this attribute lets you enter the primary key for the course rather than having the database generate it.

Create the database context

The main class that coordinates Entity Framework functionality for a given data model is the *database context* class. You create this class by deriving from the System.Data.Entity.DbContext class. In your code, you specify which entities are included in the data model. You can also customize certain Entity Framework behavior. In this project, the class is named `SchoolContext`.

- To create a folder in the ContosoUniversity project, right-click the project in **Solution Explorer** and click **Add**, and then click **New Folder**. Name the new folder *DAL* (for Data Access Layer). In that folder, create a new class file named *SchoolContext.cs*, and replace the template code with the following code:

```
using ContosoUniversity.Models;
using System.Data.Entity;
using System.Data.Entity.ModelConfiguration.Conventions;

namespace ContosoUniversity.DAL
{
    public class SchoolContext : DbContext
    {

        public SchoolContext() : base("SchoolContext")
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(DbModelBuilder modelBuilder)
        {
            modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();
        }
    }
}
```

Specify entity sets

This code creates a DbSet property for each entity set. In Entity Framework terminology, an *entity set* typically corresponds to a database table, and an *entity* corresponds to a row in the table.

> **NOTE**
> You can omit the `DbSet<Enrollment>` and `DbSet<Course>` statements and it would work the same. Entity Framework would include them implicitly because the `Student` entity references the `Enrollment` entity and the `Enrollment` entity references the `Course` entity.

Specify the connection string

The name of the connection string (which you'll add to the Web.config file later) is passed in to the constructor.

```
public SchoolContext() : base("SchoolContext")
{
}
```

You could also pass in the connection string itself instead of the name of one that is stored in the Web.config file. For more information about options for specifying the database to use, see Connection strings and models.

If you don't specify a connection string or the name of one explicitly, Entity Framework assumes that the connection string name is the same as the class name. The default connection string name in this example would then be `SchoolContext`, the same as what you're specifying explicitly.

Specify singular table names

The `modelBuilder.Conventions.Remove` statement in the OnModelCreating method prevents table names from being pluralized. If you didn't do this, the generated tables in the database would be named `Students`, `Courses`, and `Enrollments`. Instead, the table names will be `Student`, `Course`, and `Enrollment`. Developers disagree about whether table names should be pluralized or not. This tutorial uses the singular form, but the important point is that you can select whichever form you prefer by including or omitting this line of code.

Initialize DB with test data

Entity Framework can automatically create (or drop and re-create) a database for you when the application runs. You can specify that this should be done every time your application runs or only when the model is out of sync with the existing database. You can also write a `Seed` method that Entity Framework automatically calls after creating the database in order to populate it with test data.

The default behavior is to create a database only if it doesn't exist (and throw an exception if the model has changed and the database already exists). In this section, you'll specify that the database should be dropped and re-created whenever the model changes. Dropping the database causes the loss of all your data. This is generally okay during development, because the `Seed` method will run when the database is re-created and will re-create your test data. But in production you generally don't want to lose all your data every time you need to change the database schema. Later you'll see how to handle model changes by using Code First Migrations to change the database schema instead of dropping and re-creating the database.

1. In the DAL folder, create a new class file named *SchoolInitializer.cs* and replace the template code with the following code, which causes a database to be created when needed and loads test data into the new database.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Data.Entity;
using ContosoUniversity.Models;

namespace ContosoUniversity.DAL
{
    public class SchoolInitializer : System.Data.Entity.
DropCreateDatabaseIfModelChanges<SchoolContext>
    {
        protected override void Seed(SchoolContext context)
        {
            var students = new List<Student>
            {
            new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.Parse("2005-09-01")},
            new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse("2003-
09-01")},
            new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Parse("2002-09-01")},
            new Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002-09-
01")},
```

```
            new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Parse("2001-09-01")},
            new Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse("2003-
09-01")},
            new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Parse("2005-09-01")}
            };

            students.ForEach(s => context.Students.Add(s));
            context.SaveChanges();
            var courses = new List<Course>
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3,},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3,},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3,},
            new Course{CourseID=1045,Title="Calculus",Credits=4,},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4,},
            new Course{CourseID=2021,Title="Composition",Credits=3,},
            new Course{CourseID=2042,Title="Literature",Credits=4,}
            };
            courses.ForEach(s => context.Courses.Add(s));
            context.SaveChanges();
            var enrollments = new List<Enrollment>
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050,},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            enrollments.ForEach(s => context.Enrollments.Add(s));
            context.SaveChanges();
        }
    }
}
```

The `Seed` method takes the database context object as an input parameter, and the code in the method uses that object to add new entities to the database. For each entity type, the code creates a collection of new entities, adds them to the appropriate `DbSet` property, and then saves the changes to the database. It isn't necessary to call the `SaveChanges` method after each group of entities, as is done here, but doing that helps you locate the source of a problem if an exception occurs while the code is writing to the database.

2. To tell Entity Framework to use your initializer class, add an element to the `entityFramework` element in the application *Web.config* file (the one in the root project folder), as shown in the following example:

```
<entityFramework>
  <contexts>
    <context type="ContosoUniversity.DAL.SchoolContext, ContosoUniversity">
      <databaseInitializer type="ContosoUniversity.DAL.SchoolInitializer, ContosoUniversity" />
    </context>
  </contexts>
  <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory,
EntityFramework">
    <parameters>
      <parameter value="v11.0" />
    </parameters>
  </defaultConnectionFactory>
  <providers>
    <provider invariantName="System.Data.SqlClient"
type="System.Data.Entity.SqlServer.SqlProviderServices, EntityFramework.SqlServer" />
  </providers>
</entityFramework>
```

The `context type` specifies the fully qualified context class name and the assembly it's in, and the `databaseinitializer type` specifies the fully qualified name of the initializer class and the assembly it's in. (When you don't want EF to use the initializer, you can set an attribute on the `context` element: `disableDatabaseInitialization="true"`.) For more information, see Configuration File Settings.

An alternative to setting the initializer in the *Web.config* file is to do it in code by adding a `Database.SetInitializer` statement to the `Application_Start` method in the *Global.asax.cs* file. For more information, see Understanding Database Initializers in Entity Framework Code First.

The application is now set up so that when you access the database for the first time in a given run of the application, Entity Framework compares the database to the model (your `SchoolContext` and entity classes). If there's a difference, the application drops and re-creates the database.

> **NOTE**
> When you deploy an application to a production web server, you must remove or disable code that drops and re-creates the database. You'll do that in a later tutorial in this series.

Set up EF 6 to use LocalDB

LocalDB is a lightweight version of the SQL Server Express database engine. It's easy to install and configure, starts on demand, and runs in user mode. LocalDB runs in a special execution mode of SQL Server Express that enables you to work with databases as *.mdf* files. You can put LocalDB database files in the *App_Data* folder of a web project if you want to be able to copy the database with the project. The user instance feature in SQL Server Express also enables you to work with *.mdf* files, but the user instance feature is deprecated; therefore, LocalDB is recommended for working with *.mdf* files. LocalDB is installed by default with Visual Studio.

Typically, SQL Server Express is not used for production web applications. LocalDB in particular is not recommended for production use with a web application because it's not designed to work with IIS.

- In this tutorial, you'll work with LocalDB. Open the application *Web.config* file and add a `connectionStrings` element preceding the `appSettings` element, as shown in the following example. (Make sure you update the *Web.config* file in the root project folder. There's also a *Web.config* file in the *Views* subfolder that you don't need to update.)

```
<connectionStrings>
    <add name="SchoolContext" connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial
Catalog=ContosoUniversity1;Integrated Security=SSPI;" providerName="System.Data.SqlClient"/>
</connectionStrings>
<appSettings>
  <add key="webpages:Version" value="3.0.0.0" />
  <add key="webpages:Enabled" value="false" />
  <add key="ClientValidationEnabled" value="true" />
  <add key="UnobtrusiveJavaScriptEnabled" value="true" />
</appSettings>
```

The connection string you've added specifies that Entity Framework will use a LocalDB database named *ContosoUniversity1.mdf*. (The database doesn't exist yet but EF will create it.) If you want to create the database in your *App_Data* folder, you could add `AttachDBFilename=|DataDirectory|\ContosoUniversity1.mdf` to the connection string. For more information about connection strings, see SQL Server Connection Strings for ASP.NET Web Applications.

You don't actually need a connection string in the *Web.config* file. If you don't supply a connection string, Entity Framework uses a default connection string based on your context class. For more information, see Code First to a New Database.

Create controller and views

Now you'll create a web page to display data. The process of requesting the data automatically triggers the creation of the database. You'll begin by creating a new controller. But before you do that, build the project to make the model and context classes available to MVC controller scaffolding.

1. Right-click the **Controllers** folder in **Solution Explorer**, select **Add**, and then click **New Scaffolded Item**.

2. In the **Add Scaffold** dialog box, select **MVC 5 Controller with views, using Entity Framework**, and then choose **Add**.

3. In the **Add Controller** dialog box, make the following selections, and then choose **Add**:

   - Model class: **Student (ContosoUniversity.Models)**. (If you don't see this option in the drop-down list, build the project and try again.)
   - Data context class: **SchoolContext (ContosoUniversity.DAL)**.
   - Controller name: **StudentController** (not StudentsController).

- Leave the default values for the other fields.

  When you click **Add**, the scaffolder creates a *StudentController.cs* file and a set of views (*.cshtml* files) that work with the controller. In the future when you create projects that use Entity Framework, you can also take advantage of some additional functionality of the scaffolder: create your first model class, don't create a connection string, and then in the **Add Controller** box specify **New data context** by selecting the **+** button next to **Data context class**. The scaffolder will create your `DbContext` class and your connection string as well as the controller and views.

4. Visual Studio opens the *Controllers\StudentController.cs* file. You see that a class variable has been created that instantiates a database context object:

```
private SchoolContext db = new SchoolContext();
```

The `Index` action method gets a list of students from the *Students* entity set by reading the `Students` property of the database context instance:

```
public ViewResult Index()
{
    return View(db.Students.ToList());
}
```

The *Student\Index.cshtml* view displays this list in a table:

```
<table>
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.LastName)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.FirstMidName)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.EnrollmentDate)
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.LastName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.FirstMidName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}
```

5. Press Ctrl+F5 to run the project. (If you get a "Cannot create Shadow Copy" error, close the browser and try again.)

Click the **Students** tab to see the test data that the `Seed` method inserted. Depending on how narrow your browser window is, you'll see the Student tab link in the top address bar or you'll have to click the upper right corner to see the link.

View the database

When you ran the Students page and the application tried to access the database, EF discovered that there was no database and created one. EF then ran the seed method to populate the database with data.

You can use either **Server Explorer** or **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio. For this tutorial, you'll use **Server Explorer**.

1. Close the browser.
2. In **Server Explorer**, expand **Data Connections** (you may need to select the refresh button first), expand **School Context (ContosoUniversity)**, and then expand **Tables** to see the tables in your new database.
3. Right-click the **Student** table and click **Show Table Data** to see the columns that were created and the rows that were inserted into the table.
4. Close the **Server Explorer** connection.

The *ContosoUniversity1.mdf* and *.ldf* database files are in the *%USERPROFILE%* folder.

Because you're using the `DropCreateDatabaseIfModelChanges` initializer, you could now make a change to the `Student` class, run the application again, and the database would automatically be re-created to match your change. For example, if you add an `EmailAddress` property to the `Student` class, run the Students page again, and then look at the table again, you'll see a new `EmailAddress` column.

Conventions

The amount of code you had to write in order for Entity Framework to be able to create a complete database for you is minimal because of *conventions*, or assumptions that Entity Framework makes. Some of them have already been noted or were used without your being aware of them:

- The pluralized forms of entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named `ID` or *classname* `ID` are recognized as primary key properties.
- A property is interpreted as a foreign key property if it's named *<navigation property name><primary key property name>* (for example, `StudentID` for the `Student` navigation property since the `Student` entity's primary key is `ID`). Foreign key properties can also be named the same simply <primary key property name> (for example, `EnrollmentID` since the `Enrollment` entity's primary key is `EnrollmentID`).

You've seen that conventions can be overridden. For example, you specified that table names shouldn't be pluralized, and you'll see later how to explicitly mark a property as a foreign key property.

Get the code

- Creating a More Complex Data Model

Next steps

In this tutorial, you:

- Created an MVC web app
- Set up the site style
- Installed Entity Framework 6
- Created the data model
- Created the database context
- Initialized DB with test data
- Set up EF 6 to use LocalDB
- Created controller and views
- Viewed the database

Advance to the next article to learn how to review and customize the create, read, update, delete (CRUD) code in your controllers and views.

Implement basic CRUD functionality

Tutorial: Implement CRUD Functionality with the Entity Framework in ASP.NET MVC

2/20/2020 • 18 minutes to read • Edit Online

In the previous tutorial, you created an MVC application that stores and displays data using the Entity Framework (EF) 6 and SQL Server LocalDB. In this tutorial, you review and customize the create, read, update, delete (CRUD) code that the MVC scaffolding automatically creates for you in controllers and views.

> **NOTE**
>
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple and focused on teaching how to use EF 6 itself, they don't use repositories. For info about how to implement repositories, see the ASP.NET Data Access Content Map.

Here are examples of the web pages you create:

In this tutorial, you:

- Create a Details page

- Update the Create page
- Update the HttpPost Edit method
- Update the Delete page
- Close database connections
- Handle transactions

Prerequisites

- Create the Entity Framework Data Model

Create a Details page

The scaffolded code for the Students `Index` page left out the `Enrollments` property, because that property holds a collection. In the `Details` page, you'll display the contents of the collection in an HTML table.

In *Controllers\StudentController.cs*, the action method for the `Details` view uses the Find method to retrieve a single `Student` entity.

```
public ActionResult Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Student student = db.Students.Find(id);
    if (student == null)
    {
        return HttpNotFound();
    }
    return View(student);
}
```

The key value is passed to the method as the `id` parameter and comes from *route data* in the **Details** hyperlink on the Index page.

Tip: Route data

Route data is data that the model binder found in a URL segment specified in the routing table. For example, the default route specifies `controller`, `action`, and `id` segments:

```
routes.MapRoute(
    name: "Default",
    url: "{controller}/{action}/{id}",
    defaults: new { controller = "Home", action = "Index", id = UrlParameter.Optional }
);
```

In the following URL, the default route maps `Instructor` as the `controller`, `Index` as the `action` and 1 as the `id`; these are route data values.

`http://localhost:1230/Instructor/Index/1?courseID=2021`

`?courseID=2021` is a query string value. The model binder will also work if you pass the `id` as a query string value:

`http://localhost:1230/Instructor/Index?id=1&CourseID=2021`

The URLs are created by `ActionLink` statements in the Razor view. In the following code, the `id` parameter matches the default route, so `id` is added to the route data.

```
@Html.ActionLink("Select", "Index", new { id = item.PersonID  })
```

In the following code, `courseID` doesn't match a parameter in the default route, so it's added as a query string.

```
@Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
```

To create the Details page

1. Open *Views\Student\Details.cshtml*.

   Each field is displayed using a `DisplayFor` helper, as shown in the following example:

   ```
   <dt>
       @Html.DisplayNameFor(model => model.LastName)
   </dt>
   <dd>
       @Html.DisplayFor(model => model.LastName)
   </dd>
   ```

2. After the `EnrollmentDate` field and immediately before the closing `</dl>` tag, add the highlighted code to display a list of enrollments, as shown in the following example:

   ```
   <dt>
               @Html.DisplayNameFor(model => model.EnrollmentDate)
           </dt>

           <dd>
               @Html.DisplayFor(model => model.EnrollmentDate)
           </dd>
           <dt>
               @Html.DisplayNameFor(model => model.Enrollments)
           </dt>
           <dd>
               <table class="table">
                   <tr>
                       <th>Course Title</th>
                       <th>Grade</th>
                   </tr>
                   @foreach (var item in Model.Enrollments)
                   {
                       <tr>
                           <td>
                               @Html.DisplayFor(modelItem => item.Course.Title)
                           </td>
                           <td>
                               @Html.DisplayFor(modelItem => item.Grade)
                           </td>
                       </tr>
                   }
               </table>
           </dd>
       </dl>
   </div>
   <p>
       @Html.ActionLink("Edit", "Edit", new { id = Model.ID }) |
       @Html.ActionLink("Back to List", "Index")
   </p>
   ```

   If code indentation is wrong after you paste the code, press **Ctrl**+**K**, **Ctrl**+**D** to format it.

   This code loops through the entities in the `Enrollments` navigation property. For each `Enrollment` entity in

the property, it displays the course title and the grade. The course title is retrieved from the `Course` entity that's stored in the `Course` navigation property of the `Enrollments` entity. All of this data is retrieved from the database automatically when it's needed. In other words, you are using lazy loading here. You did not specify *eager loading* for the `Courses` navigation property, so the enrollments were not retrieved in the same query that got the students. Instead, the first time you try to access the `Enrollments` navigation property, a new query is sent to the database to retrieve the data. You can read more about lazy loading and eager loading in the Reading Related Data tutorial later in this series.

3. Open the Details page by starting the program (**Ctrl+F5**), selecting the **Students** tab, and then clicking the **Details** link for Alexander Carson. (If you press **Ctrl+F5** while the *Details.cshtml* file is open, you get an HTTP 400 error. This is because Visual Studio tries to run the Details page, but it wasn't reached from a link that specifies the student to display. If that happens, remove "Student/Details" from the URL and try again, or, close the browser, right-click the project, and click **View** > **View in Browser**.)

   You see the list of courses and grades for the selected student.

4. Close the browser.

Update the Create page

1. In *Controllers\StudentController.cs*, replace the HttpPostAttribute `Create` action method with the following code. This code adds a `try-catch` block and removes `ID` from the BindAttribute attribute for the scaffolded method:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create([Bind(Include = "LastName, FirstMidName, EnrollmentDate")]Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            db.Students.Add(student);
            db.SaveChanges();
            return RedirectToAction("Index");
        }
    }
    catch (DataException /* dex */)
    {
        //Log the error (uncomment dex variable name and add a line here to write a log.
        ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists
see your system administrator.");
    }
    return View(student);
}
```

   This code adds the `Student` entity created by the ASP.NET MVC model binder to the `Students` entity set and then saves the changes to the database. *Model binder* refers to the ASP.NET MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a `Student` entity for you using property values from the `Form` collection.

   You removed `ID` from the Bind attribute because `ID` is the primary key value which SQL Server will set automatically when the row is inserted. Input from the user does not set the `ID` value.

   Security warning - The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery attacks. It requires a corresponding `Html.AntiForgeryToken()` statement in the view, which you'll see later.

   The `Bind` attribute is one way to protect against *over-posting* in create scenarios. For example, suppose the

`Student` entity includes a `Secret` property that you don't want this web page to set.

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }

    public virtual ICollection<Enrollment> Enrollments { get; set; }
}
```

Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as fiddler, or write some JavaScript, to post a `Secret` form value. Without the BindAttribute attribute limiting the fields that the model binder uses when it creates a `Student` instance, the model binder would pick up that `Secret` form value and use it to create the `Student` entity instance. Then whatever value the hacker specified for the `Secret` form field would be updated in your database. The following image shows the fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.

The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although you never intended that the web page be able to set that property.

It's best to use the `Include` parameter with the `Bind` attribute to *whitelist* fields. It's also possible to use the `Exclude` parameter to *blacklist* fields you want to exclude. The reason `Include` is more secure is that when you add a new property to the entity, the new field is not automatically protected by an `Exclude` list.

You can prevent overposting in edit scenarios is by reading the entity from the database first and then calling `TryUpdateModel`, passing in an explicit allowed properties list. That is the method used in these tutorials.

An alternative way to prevent overposting that is preferred by many developers is to use view models rather than entity classes with model binding. Include only the properties you want to update in the view model. Once the MVC model binder has finished, copy the view model properties to the entity instance, optionally using a tool such as AutoMapper. Use db.Entry on the entity instance to set its state to Unchanged, and then set Property("PropertyName").IsModified to true on each entity property that is included in the view model. This method works in both edit and create scenarios.

Other than the `Bind` attribute, the `try-catch` block is the only change you've made to the scaffolded code. If an exception that derives from DataException is caught while the changes are being saved, a generic error message is displayed. DataException exceptions are sometimes caused by something external to the application rather than a programming error, so the user is advised to try again. Although not implemented in this sample, a production quality application would log the exception. For more information, see the **Log for insight** section in Monitoring and Telemetry (Building Real-World Cloud Apps with Azure).

The code in *Views\Student\Create.cshtml* is similar to what you saw in *Details.cshtml*, except that `EditorFor` and `ValidationMessageFor` helpers are used for each field instead of `DisplayFor`. Here is the relevant code:

```
<div class="form-group">
    @Html.LabelFor(model => model.LastName, new { @class = "control-label col-md-2" })
    <div class="col-md-10">
        @Html.EditorFor(model => model.LastName)
        @Html.ValidationMessageFor(model => model.LastName)
    </div>
</div>
```

Create.cshtml also includes `@Html.AntiForgeryToken()`, which works with the `ValidateAntiForgeryToken` attribute in the controller to help prevent cross-site request forgery attacks.

No changes are required in *Create.cshtml*.

2. Run the page by starting the program, selecting the **Students** tab, and then clicking **Create New**.

3. Enter names and an invalid date and click **Create** to see the error message.

   This is server-side validation that you get by default. In a later tutorial, you'll see how to add attributes that generate code for client-side validation. The following highlighted code shows the model validation check in the **Create** method.

```
if (ModelState.IsValid)
{
    db.Students.Add(student);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

4. Change the date to a valid value and click **Create** to see the new student appear in the **Index** page.

5. Close the browser.

Update HttpPost Edit method

1. Replace the HttpPostAttribute `Edit` action method with the following code:

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public ActionResult EditPost(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    var studentToUpdate = db.Students.Find(id);
    if (TryUpdateModel(studentToUpdate, "",
       new string[] { "LastName", "FirstMidName", "EnrollmentDate" }))
    {
        try
        {
            db.SaveChanges();

            return RedirectToAction("Index");
        }
        catch (DataException /* dex */)
        {
            //Log the error (uncomment dex variable name and add a line here to write a log.
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem
persists, see your system administrator.");
        }
    }
    return View(studentToUpdate);
}
```

NOTE

In *Controllers\StudentController.cs*, the `HttpGet Edit` method (the one without the `HttpPost` attribute) uses the `Find` method to retrieve the selected `Student` entity, as you saw in the `Details` method. You don't need to change this method.

These changes implement a security best practice to prevent overposting, The scaffolder generated a `Bind` attribute and added the entity created by the model binder to the entity set with a Modified flag. That code is no longer recommended because the `Bind` attribute clears out any pre-existing data in fields not listed in the `Include` parameter. In the future, the MVC controller scaffolder will be updated so that it doesn't generate `Bind` attributes for Edit methods.

The new code reads the existing entity and calls TryUpdateModel to update fields from user input in the posted form data. The Entity Framework's automatic change tracking sets the EntityState.Modified flag on the entity. When the SaveChanges method is called, the Modified flag causes the Entity Framework to create SQL statements to update the database row. Concurrency conflicts are ignored, and all columns of the database row are updated, including those that the user didn't change. (A later tutorial shows how to handle concurrency conflicts, and if you only want individual fields to be updated in the database, you can set the entity to EntityState.Unchanged and set individual fields to EntityState.Modified.)

To prevent overposting, the fields that you want to be updateable by the Edit page are whitelisted in the `TryUpdateModel` parameters. Currently there are no extra fields that you're protecting, but listing the fields that you want the model binder to bind ensures that if you add fields to the data model in the future, they're automatically protected until you explicitly add them here.

As a result of these changes, the method signature of the HttpPost Edit method is the same as the HttpGet edit method; therefore you've renamed the method EditPost.

TIP

Entity States and the Attach and SaveChanges Methods

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the Add method, that entity's state is set to `Added`. Then when you call the SaveChanges method, the database context issues a SQL `INSERT` command.

An entity may be in one of the following states:

- `Added`. The entity does not yet exist in the database. The `SaveChanges` method must issue an `INSERT` statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.
- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method must issue an `UPDATE` statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method must issue a `DELETE` statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. In a desktop type of application, you read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL `UPDATE` statement that updates only the actual properties that you changed.

The disconnected nature of web apps doesn't allow for this continuous sequence. The DbContext that reads an entity is disposed after a page is rendered. When the `HttpPost` `Edit` action method is called, a new request is made and you have a new instance of the DbContext, so you have to manually set the entity state to `Modified.` Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the context has no way to know which properties you changed.

If you want the SQL `Update` statement to update only the fields that the user actually changed, you can save the original values in some way (such as hidden fields) so that they are available when the `HttpPost` `Edit` method is called. Then you can create a `Student` entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges.` For more information, see Entity states and SaveChanges and Local Data.

The HTML and Razor code in *Views\Student\Edit.cshtml* is similar to what you saw in *Create.cshtml*, and no changes are required.

2. Run the page by starting the program, selecting the **Students** tab, and then clicking an **Edit** hyperlink.

3. Change some of the data and click **Save**. You see the changed data in the Index page.

4. Close the browser.

Update the Delete page

In *Controllers\StudentController.cs*, the template code for the HttpGetAttribute `Delete` method uses the `Find` method to retrieve the selected `Student` entity, as you saw in the `Details` and `Edit` methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that is called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the `HttpPost` `Delete` method is

called and then that method actually performs the delete operation.

You'll add a `try-catch` block to the HttpPostAttribute `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the HttpPostAttribute `Delete` method calls the HttpGetAttribute `Delete` method, passing it a parameter that indicates that an error has occurred. The HttpGetAttribute `Delete` method then redisplays the confirmation page along with the error message, giving the user an opportunity to cancel or try again.

1. Replace the HttpGetAttribute `Delete` action method with the following code, which manages error reporting:

```
public ActionResult Delete(int? id, bool? saveChangesError=false)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    if (saveChangesError.GetValueOrDefault())
    {
        ViewBag.ErrorMessage = "Delete failed. Try again, and if the problem persists see your system
administrator.";
    }
    Student student = db.Students.Find(id);
    if (student == null)
    {
        return HttpNotFound();
    }
    return View(student);
}
```

   This code accepts an optional parameter that indicates whether the method was called after a failure to save changes. This parameter is `false` when the `HttpGet` `Delete` method is called without a previous failure. When it is called by the `HttpPost` `Delete` method in response to a database update error, the parameter is `true` and an error message is passed to the view.

2. Replace the HttpPostAttribute `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Delete(int id)
{
    try
    {
        Student student = db.Students.Find(id);
        db.Students.Remove(student);
        db.SaveChanges();
    }
    catch (DataException/* dex */)
    {
        //Log the error (uncomment dex variable name and add a line here to write a log.
        return RedirectToAction("Delete", new { id = id, saveChangesError = true });
    }
    return RedirectToAction("Index");
}
```

   This code retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL `DELETE` command is generated. You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code named the `HttpPost` `Delete` method `DeleteConfirmed` to give the `HttpPost` method a unique signature. (The CLR requires overloaded methods

to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the `HttpPost` and `HttpGet` delete methods.

If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query to retrieve the row by replacing the lines of code that call the `Find` and `Remove` methods with the following code:

```
Student studentToDelete = new Student() { ID = id };
db.Entry(studentToDelete).State = EntityState.Deleted;
```

This code instantiates a `Student` entity using only the primary key value and then sets the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity.

As noted, the `HttpGet` `Delete` method doesn't delete the data. Performing a delete operation in response to a GET request (or for that matter, performing any edit operation, create operation, or any other operation that changes data) creates a security risk. For more information, see ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes on Stephen Walther's blog.

3. In *Views\Student\Delete.cshtml*, add an error message between the `h2` heading and the `h3` heading, as shown in the following example:

```
<h2>Delete</h2>
<p class="error">@ViewBag.ErrorMessage</p>
<h3>Are you sure you want to delete this?</h3>
```

4. Run the page by starting the program, selecting the **Students** tab, and then clicking a **Delete** hyperlink.

5. Choose **Delete** on the page that says **Are you sure you want to delete this?**.

   The Index page displays without the deleted student. (You'll see an example of the error handling code in action in the concurrency tutorial.)

Close database connections

To close database connections and free up the resources they hold as soon as possible, dispose the context instance when you are done with it. That is why the scaffolded code provides a Dispose method at the end of the `StudentController` class in *StudentController.cs*, as shown in the following example:

```
protected override void Dispose(bool disposing)
{
    if (disposing)
    {
        db.Dispose();
    }
    base.Dispose(disposing);
}
```

The base `Controller` class already implements the `IDisposable` interface, so this code simply adds an override to the `Dispose(bool)` method to explicitly dispose the context instance.

Handle transactions

By default the Entity Framework implicitly implements transactions. In scenarios where you make changes to multiple rows or tables and then call `SaveChanges`, the Entity Framework automatically makes sure that either all of your changes succeed or all fail. If some changes are done first and then an error happens, those changes are

automatically rolled back. For scenarios where you need more control—for example, if you want to include operations done outside of Entity Framework in a transaction—see Working with Transactions.

Get the code

Download Completed Project

Additional resources

You now have a complete set of pages that perform simple CRUD operations for `Student` entities. You used MVC helpers to generate UI elements for data fields. For more info about MVC helpers, see Rendering a Form Using HTML Helpers (the article is for MVC 3 but is still relevant for MVC 5).

Links to other EF 6 resources can be found in ASP.NET Data Access - Recommended Resources.

Next steps

In this tutorial, you:

- Created a Details page
- Updated the Create page
- Updated the HttpPost Edit method
- Updated the Delete page
- Closed database connections
- Handled transactions

Advance to the next article to learn how to add sorting, filtering, and paging to the project.

Sorting, Filtering, and Paging

Tutorial: Add sorting, filtering, and paging with the Entity Framework in an ASP.NET MVC application

2/20/2020 • 14 minutes to read • Edit Online

In the previous tutorial, you implemented a set of web pages for basic CRUD operations for `Student` entities. In this tutorial you add sorting, filtering, and paging functionality to the **Students** Index page. You also create a simple grouping page.

The following image shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.

In this tutorial, you:

- Add column sort links
- Add a Search box
- Add paging
- Create an About page

Prerequisites

- Implementing Basic CRUD Functionality

Add column sort links

To add sorting to the Student Index page, you'll change the `Index` method of the `Student` controller and add code to the `Student` Index view.

Add sorting functionality to the Index method

- In *Controllers\StudentController.cs*, replace the `Index` method with the following code:

```
public ActionResult Index(string sortOrder)
{
   ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
   ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";
   var students = from s in db.Students
                  select s;
   switch (sortOrder)
   {
      case "name_desc":
         students = students.OrderByDescending(s => s.LastName);
         break;
      case "Date":
         students = students.OrderBy(s => s.EnrollmentDate);
         break;
      case "date_desc":
         students = students.OrderByDescending(s => s.EnrollmentDate);
         break;
      default:
         students = students.OrderBy(s => s.LastName);
         break;
   }
   return View(students.ToList());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET MVC as a parameter to the action method. The parameter is a string that's either "Name" or "Date", optionally followed by an underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by `LastName`, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewBag` variables are used so that the view can configure the column heading hyperlinks with the appropriate query string values:

```
ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, `ViewBag.NameSortParm` should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an IQueryable<T> variable before the `switch` statement, modifies it in the `switch` statement, and calls the `ToList` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query is not executed until you convert the `IQueryable` object into a collection by calling a method such as `ToList`. Therefore, this code results in a single query that is not executed until the `return View` statement.

As an alternative to writing different LINQ statements for each sort order, you can dynamically create a LINQ statement. For information about dynamic LINQ, see Dynamic LINQ.

Add column heading hyperlinks to the Student index view

1. In *Views\Student\Index.cshtml*, replace the `<tr>` and `<th>` elements for the heading row with the highlighted code:

```
<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table class="table">
    <tr>
        <th>
            @Html.ActionLink("Last Name", "Index", new { sortOrder = ViewBag.NameSortParm })
        </th>
        <th>First Name
        </th>
        <th>
            @Html.ActionLink("Enrollment Date", "Index", new { sortOrder = ViewBag.DateSortParm })
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
```

   This code uses the information in the `ViewBag` properties to set up hyperlinks with the appropriate query string values.

2. Run the page and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.

   After you click the **Last Name** heading, students are displayed in descending last name order.

Add a Search box

To add filtering to the Students index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box lets you enter a string to search for in the first name and last name fields.

Add filtering functionality to the Index method

- In *Controllers\StudentController.cs*, replace the `Index` method with the following code (the changes are highlighted):

```
public ViewResult Index(string sortOrder, string searchString)
{
    ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in db.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    return View(students.ToList());
}
```

The code adds a `searchString` parameter to the `Index` method. The search string value is received from a text box that you'll add to the Index view. It also adds a `where` clause to the LINQ statement that selects only students whose first name or last name contains the search string. The statement that adds the Where clause executes only if there's a value to search for.

> **NOTE**
>
> In many cases you can call the same method either on an Entity Framework entity set or as an extension method on an in-memory collection. The results are normally the same but in some cases may be different.
>
> For example, the .NET Framework implementation of the `Contains` method returns all rows when you pass an empty string to it, but the Entity Framework provider for SQL Server Compact 4.0 returns zero rows for empty strings. Therefore the code in the example (putting the `Where` statement inside an `if` statement) makes sure that you get the same results for all versions of SQL Server. Also, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but Entity Framework SQL Server providers perform case-insensitive comparisons by default. Therefore, calling the `ToUpper` method to make the test explicitly case-insensitive ensures that results do not change when you change the code later to use a repository, which will return an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the .NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.)
>
> Null handling may also be different for different database providers or when you use an `IQueryable` object compared to when you use an `IEnumerable` collection. For example, in some scenarios a `Where` condition such as `table.Column != 0` may not return columns that have `null` as the value. By default, EF generates additional SQL operators to make equality between null values work in the database like it works in memory, but you can set the UseDatabaseNullSemantics flag in EF6 or call the UseRelationalNulls method in EF Core to configure this behavior.

Add a search box to the Student index view

1. In *Views\Student\Index.cshtml*, add the highlighted code immediately before the opening `table` tag in order to create a caption, a text box, and a **Search** button.

```
<p>
    @Html.ActionLink("Create New", "Create")
</p>

@using (Html.BeginForm())
{
    <p>
        Find by name: @Html.TextBox("SearchString")
        <input type="submit" value="Search" /></p>
}

<table>
    <tr>
```

2. Run the page, enter a search string, and click **Search** to verify that filtering is working.

   Notice the URL doesn't contain the "an" search string, which means that if you bookmark this page, you won't get the filtered list when you use the bookmark. This applies also to the column sort links, as they will sort the whole list. You'll change the **Search** button to use query strings for filter criteria later in the tutorial.

Add paging

To add paging to the Students index page, you'll start by installing the **PagedList.Mvc** NuGet package. Then you'll make additional changes in the `Index` method and add paging links to the `Index` view. **PagedList.Mvc** is one of many good paging and sorting packages for ASP.NET MVC, and its use here is intended only as an example, not as a recommendation for it over other options.

Install the PagedList.MVC NuGet package

The NuGet **PagedList.Mvc** package automatically installs the **PagedList** package as a dependency. The **PagedList** package installs a `PagedList` collection type and extension methods for `IQueryable` and `IEnumerable` collections. The extension methods create a single page of data in a `PagedList` collection out of your `IQueryable` or `IEnumerable`, and the `PagedList` collection provides several properties and methods that facilitate paging. The **PagedList.Mvc** package installs a paging helper that displays the paging buttons.

1. From the **Tools** menu, select **NuGet Package Manager** and then **Package Manager Console**.

2. In the **Package Manager Console** window, make sure the **Package source** is **nuget.org** and the **Default project** is **ContosoUniversity**, and then enter the following command:

```
Install-Package PagedList.Mvc
```

3. Build the project.

Add paging functionality to the Index method

1. In *Controllers\StudentController.cs*, add a `using` statement for the `PagedList` namespace:

```
using PagedList;
```

2. Replace the `Index` method with the following code:

```
public ViewResult Index(string sortOrder, string currentFilter, string searchString, int? page)
{
   ViewBag.CurrentSort = sortOrder;
   ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
   ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";

   if (searchString != null)
   {
      page = 1;
   }
   else
   {
      searchString = currentFilter;
   }

   ViewBag.CurrentFilter = searchString;

   var students = from s in db.Students
                  select s;
   if (!String.IsNullOrEmpty(searchString))
   {
      students = students.Where(s => s.LastName.Contains(searchString)
                              || s.FirstMidName.Contains(searchString));
   }
   switch (sortOrder)
   {
      case "name_desc":
         students = students.OrderByDescending(s => s.LastName);
         break;
      case "Date":
         students = students.OrderBy(s => s.EnrollmentDate);
         break;
      case "date_desc":
         students = students.OrderByDescending(s => s.EnrollmentDate);
         break;
      default:  // Name ascending
         students = students.OrderBy(s => s.LastName);
         break;
   }

   int pageSize = 3;
   int pageNumber = (page ?? 1);
   return View(students.ToPagedList(pageNumber, pageSize));
}
```

This code adds a `page` parameter, a current sort order parameter, and a current filter parameter to the method signature:

```
public ActionResult Index(string sortOrder, string currentFilter, string searchString, int? page)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters are null. If a paging link is clicked, the `page` variable contains the page number to display.

A `ViewBag` property provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging:

```
ViewBag.CurrentSort = sortOrder;
```

Another property, `ViewBag.CurrentFilter`, provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed. If the search string is changed during paging, the

page has to be reset to 1, because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the submit button is pressed. In that case, the `searchString` parameter is not null.

```
if (searchString != null)
{
    page = 1;
}
else
{
    searchString = currentFilter;
}
```

At the end of the method, the `ToPagedList` extension method on the students `IQueryable` object converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view:

```
int pageSize = 3;
int pageNumber = (page ?? 1);
return View(students.ToPagedList(pageNumber, pageSize));
```

The `ToPagedList` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(page ?? 1)` means return the value of `page` if it has a value, or return 1 if `page` is null.

Add paging links to the Student index view

1. In *Views\Student\Index.cshtml*, replace the existing code with the following code. The changes are highlighted.

```
@model PagedList.IPagedList<ContosoUniversity.Models.Student>
@using PagedList.Mvc;
<link href="~/Content/PagedList.css" rel="stylesheet" type="text/css" />

@{
    ViewBag.Title = "Students";
}

<h2>Students</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
@using (Html.BeginForm("Index", "Student", FormMethod.Get))
{
    <p>
        Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
        <input type="submit" value="Search" />
    </p>
}
<table class="table">
    <tr>
        <th>
            @Html.ActionLink("Last Name", "Index", new { sortOrder = ViewBag.NameSortParm,
currentFilter=ViewBag.CurrentFilter })
        </th>
        <th>
            First Name
        </th>
        <th>
            @Html.ActionLink("Enrollment Date", "Index", new { sortOrder = ViewBag.DateSortParm,
currentFilter=ViewBag.CurrentFilter })
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.LastName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.FirstMidName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}

</table>
<br />
Page @(Model.PageCount < Model.PageNumber ? 0 : Model.PageNumber) of @Model.PageCount

@Html.PagedListPager(Model, page => Url.Action("Index",
    new { page, sortOrder = ViewBag.CurrentSort, currentFilter = ViewBag.CurrentFilter }))
```

The `@model` statement at the top of the page specifies that the view now gets a `PagedList` object instead of a `List` object.

The `using` statement for `PagedList.Mvc` gives access to the MVC helper for the paging buttons.

The code uses an overload of BeginForm that allows it to specify FormMethod.Get.

```
@using (Html.BeginForm("Index", "Student", FormMethod.Get))
{
    <p>
        Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
        <input type="submit" value="Search" />
    </p>
}
```

The default BeginForm submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines for the use of HTTP GET recommend that you should use GET when the action does not result in an update.

The text box is initialized with the current search string so when you click a new page you can see the current search string.

```
Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
```

The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

```
@Html.ActionLink("Last Name", "Index", new { sortOrder=ViewBag.NameSortParm,
currentFilter=ViewBag.CurrentFilter })
```

The current page and total number of pages are displayed.

```
Page @(Model.PageCount < Model.PageNumber ? 0 : Model.PageNumber) of @Model.PageCount
```

If there are no pages to display, "Page 0 of 0" is shown. (In that case the page number is greater than the page count because `Model.PageNumber` is 1, and `Model.PageCount` is 0.)

The paging buttons are displayed by the `PagedListPager` helper:

```
@Html.PagedListPager( Model, page => Url.Action("Index", new { page }) )
```

The `PagedListPager` helper provides a number of options that you can customize, including URLs and styling. For more information, see TroyGoode / PagedList on the GitHub site.

2. Run the page.

   Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About page

For the Contoso University website's About page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Modify the `About` method in the `Home` controller.

- Modify the `About` view.

Create the View Model

Create a *ViewModels* folder in the project folder. In that folder, add a class file *EnrollmentDateGroup.cs* and replace the template code with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.ViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

1. In *HomeController.cs*, add the following `using` statements at the top of the file:

   ```
   using ContosoUniversity.DAL;
   using ContosoUniversity.ViewModels;
   ```

2. Add a class variable for the database context immediately after the opening curly brace for the class:

   ```
   public class HomeController : Controller
   {
       private SchoolContext db = new SchoolContext();
   ```

3. Replace the `About` method with the following code:

   ```
   public ActionResult About()
   {
       IQueryable<EnrollmentDateGroup> data = from student in db.Students
                  group student by student.EnrollmentDate into dateGroup
                  select new EnrollmentDateGroup()
                  {
                      EnrollmentDate = dateGroup.Key,
                      StudentCount = dateGroup.Count()
                  };
       return View(data.ToList());
   }
   ```

   The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

4. Add a `Dispose` method:

   ```
   protected override void Dispose(bool disposing)
   {
       db.Dispose();
       base.Dispose(disposing);
   }
   ```

Modify the About View

1. Replace the code in the *Views\Home\About.cshtml* file with the following code:

```
@model IEnumerable<ContosoUniversity.ViewModels.EnrollmentDateGroup>

@{
    ViewBag.Title = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
        <td>
            @item.StudentCount
        </td>
    </tr>
}
</table>
```

2. Run the app and click the **About** link.

   The count of students for each enrollment date displays in a table.

Get the code

Next steps

In this tutorial, you:

- Add column sort links
- Add a Search box
- Add paging
- Create an About page

Advance to the next article to learn how to use connection resiliency and command interception.

Connection resiliency and command interception

Tutorial: Use connection resiliency and command interception with Entity Framework in an ASP.NET MVC app

2/20/2020 • 17 minutes to read • Edit Online

So far the application has been running locally in IIS Express on your development computer. To make a real application available for other people to use over the Internet, you have to deploy it to a web hosting provider, and you have to deploy the database to a database server.

In this tutorial you'll learn how to use connection resiliency and command interception. They are two important features of Entity Framework 6 that are especially valuable when you are deploying to the cloud environment: connection resiliency (automatic retries for transient errors) and command interception (catch all SQL queries sent to the database in order to log or change them).

This connection resiliency and command interception tutorial is optional. If you skip this tutorial, a few minor adjustments will have to be made in subsequent tutorials.

In this tutorial, you:

- Enable connection resiliency
- Enable command interception
- Test the new configuration

Prerequisites

- Sorting, Filtering, and Paging

Enable connection resiliency

When you deploy the application to Windows Azure, you'll deploy the database to Windows Azure SQL Database, a cloud database service. Transient connection errors are typically more frequent when you connect to a cloud database service than when your web server and your database server are directly connected together in the same data center. Even if a cloud web server and a cloud database service are hosted in the same data center, there are more network connections between them that can have problems, such as load balancers.

Also a cloud service is typically shared by other users, which means its responsiveness can be affected by them. And your access to the database might be subject to throttling. Throttling means the database service throws exceptions when you try to access it more frequently than is allowed in your Service Level Agreement (SLA).

Many or most connection problems when you're accessing a cloud service are transient, that is, they resolve themselves in a short period of time. So when you try a database operation and get a type of error that is typically transient, you could try the operation again after a short wait, and the operation might be successful. You can provide a much better experience for your users if you handle transient errors by automatically trying again, making most of them invisible to the customer. The connection resiliency feature in Entity Framework 6 automates that process of retrying failed SQL queries.

The connection resiliency feature must be configured appropriately for a particular database service:

- It has to know which exceptions are likely to be transient. You want to retry errors caused by a temporary loss in network connectivity, not errors caused by program bugs, for example.

- It has to wait an appropriate amount of time between retries of a failed operation. You can wait longer between retries for a batch process than you can for an online web page where a user is waiting for a response.
- It has to retry an appropriate number of times before it gives up. You might want to retry more times in a batch process that you would in an online application.

You can configure these settings manually for any database environment supported by an Entity Framework provider, but default values that typically work well for an online application that uses Windows Azure SQL Database have already been configured for you, and those are the settings you'll implement for the Contoso University application.

All you have to do to enable connection resiliency is create a class in your assembly that derives from the DbConfiguration class, and in that class set the SQL Database *execution strategy*, which in EF is another term for *retry policy*.

1. In the DAL folder, add a class file named *SchoolConfiguration.cs*.

2. Replace the template code with the following code:

```
using System.Data.Entity;
using System.Data.Entity.SqlServer;

namespace ContosoUniversity.DAL
{
    public class SchoolConfiguration : DbConfiguration
    {
        public SchoolConfiguration()
        {
            SetExecutionStrategy("System.Data.SqlClient", () => new SqlAzureExecutionStrategy());
        }
    }
}
```

   The Entity Framework automatically runs the code it finds in a class that derives from `DbConfiguration`. You can use the `DbConfiguration` class to do configuration tasks in code that you would otherwise do in the *Web.config* file. For more information, see EntityFramework Code-Based Configuration.

3. In *StudentController.cs*, add a `using` statement for `System.Data.Entity.Infrastructure`.

```
using System.Data.Entity.Infrastructure;
```

4. Change all of the `catch` blocks that catch `DataException` exceptions so that they catch `RetryLimitExceededException` exceptions instead. For example:

```
catch (RetryLimitExceededException /* dex */)
{
    //Log the error (uncomment dex variable name and add a line here to write a log.
    ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists see
your system administrator.");
}
```

   You were using `DataException` to try to identify errors that might be transient in order to give a friendly "try again" message. But now that you've turned on a retry policy, the only errors likely to be transient will already have been tried and failed several times and the actual exception returned will be wrapped in the `RetryLimitExceededException` exception.

For more information, see Entity Framework Connection Resiliency / Retry Logic.

Enable command interception

Now that you've turned on a retry policy, how do you test to verify that it is working as expected? It's not so easy to force a transient error to happen, especially when you're running locally, and it would be especially difficult to integrate actual transient errors into an automated unit test. To test the connection resiliency feature, you need a way to intercept queries that Entity Framework sends to SQL Server and replace the SQL Server response with an exception type that is typically transient.

You can also use query interception in order to implement a best practice for cloud applications: log the latency and success or failure of all calls to external services such as database services. EF6 provides a dedicated logging API that can make it easier to do logging, but in this section of the tutorial you'll learn how to use the Entity Framework's interception feature directly, both for logging and for simulating transient errors.

Create a logging interface and class

A best practice for logging is to do it by using an interface rather than hard-coding calls to System.Diagnostics.Trace or a logging class. That makes it easier to change your logging mechanism later if you ever need to do that. So in this section you'll create the logging interface and a class to implement it./p>

1. Create a folder in the project and name it *Logging*.

2. In the *Logging* folder, create a class file named *ILogger.cs*, and replace the template code with the following code:

```
using System;

namespace ContosoUniversity.Logging
{
    public interface ILogger
    {
        void Information(string message);
        void Information(string fmt, params object[] vars);
        void Information(Exception exception, string fmt, params object[] vars);

        void Warning(string message);
        void Warning(string fmt, params object[] vars);
        void Warning(Exception exception, string fmt, params object[] vars);

        void Error(string message);
        void Error(string fmt, params object[] vars);
        void Error(Exception exception, string fmt, params object[] vars);

        void TraceApi(string componentName, string method, TimeSpan timespan);
        void TraceApi(string componentName, string method, TimeSpan timespan, string properties);
        void TraceApi(string componentName, string method, TimeSpan timespan, string fmt, params
object[] vars);
    }
}
```

   The interface provides three tracing levels to indicate the relative importance of logs, and one designed to provide latency information for external service calls such as database queries. The logging methods have overloads that let you pass in an exception. This is so that exception information including stack trace and inner exceptions is reliably logged by the class that implements the interface, instead of relying on that being done in each logging method call throughout the application.

   The TraceApi methods enable you to track the latency of each call to an external service such as SQL Database.

3. In the *Logging* folder, create a class file named *Logger.cs*, and replace the template code with the following code:

```
using System;
using System.Diagnostics;
using System.Text;

namespace ContosoUniversity.Logging
{
    public class Logger : ILogger
    {
        public void Information(string message)
        {
            Trace.TraceInformation(message);
        }

        public void Information(string fmt, params object[] vars)
        {
            Trace.TraceInformation(fmt, vars);
        }

        public void Information(Exception exception, string fmt, params object[] vars)
        {
            Trace.TraceInformation(FormatExceptionMessage(exception, fmt, vars));
        }

        public void Warning(string message)
        {
            Trace.TraceWarning(message);
        }

        public void Warning(string fmt, params object[] vars)
        {
            Trace.TraceWarning(fmt, vars);
        }

        public void Warning(Exception exception, string fmt, params object[] vars)
        {
            Trace.TraceWarning(FormatExceptionMessage(exception, fmt, vars));
        }

        public void Error(string message)
        {
            Trace.TraceError(message);
        }

        public void Error(string fmt, params object[] vars)
        {
            Trace.TraceError(fmt, vars);
        }

        public void Error(Exception exception, string fmt, params object[] vars)
        {
            Trace.TraceError(FormatExceptionMessage(exception, fmt, vars));
        }

        public void TraceApi(string componentName, string method, TimeSpan timespan)
        {
            TraceApi(componentName, method, timespan, "");
        }

        public void TraceApi(string componentName, string method, TimeSpan timespan, string fmt, params
object[] vars)
        {
            TraceApi(componentName, method, timespan, string.Format(fmt, vars));
        }
        public void TraceApi(string componentName, string method, TimeSpan timespan, string properties)
        {
            string message = String.Concat("Component:", componentName, ";Method:", method,
";Timespan:", timespan.ToString(), ";Properties:", properties);
            Trace.TraceInformation(message);
```

```
        }

        private static string FormatExceptionMessage(Exception exception, string fmt, object[] vars)
        {
            // Simple exception formatting: for a more comprehensive version see
            // https://code.msdn.microsoft.com/windowsazure/Fix-It-app-for-Building-cdd80df4
            var sb = new StringBuilder();
            sb.Append(string.Format(fmt, vars));
            sb.Append(" Exception: ");
            sb.Append(exception.ToString());
            return  sb.ToString();
        }
    }
}
```

The implementation uses System.Diagnostics to do the tracing. This is a built-in feature of .NET which makes it easy to generate and use tracing information. There are many "listeners" you can use with System.Diagnostics tracing, to write logs to files, for example, or to write them to blob storage in Azure. See some of the options, and links to other resources for more information, in Troubleshooting Azure Web Sites in Visual Studio. For this tutorial you'll only look at logs in the Visual Studio **Output** window.

In a production application you might want to consider tracing packages other than System.Diagnostics, and the ILogger interface makes it relatively easy to switch to a different tracing mechanism if you decide to do that.

Create interceptor classes

Next you'll create the classes that the Entity Framework will call into every time it is going to send a query to the database, one to simulate transient errors and one to do logging. These interceptor classes must derive from the `DbCommandInterceptor` class. In them you write method overrides that are automatically called when query is about to be executed. In these methods you can examine or log the query that is being sent to the database, and you can change the query before it's sent to the database or return something to Entity Framework yourself without even passing the query to the database.

1. To create the interceptor class that will log every SQL query that is sent to the database, create a class file named *SchoolInterceptorLogging.cs* in the *DAL* folder, and replace the template code with the following code:

```
using System;
using System.Data.Common;
using System.Data.Entity;
using System.Data.Entity.Infrastructure.Interception;
using System.Data.Entity.SqlServer;
using System.Data.SqlClient;
using System.Diagnostics;
using System.Reflection;
using System.Linq;
using ContosoUniversity.Logging;

namespace ContosoUniversity.DAL
{
    public class SchoolInterceptorLogging : DbCommandInterceptor
    {
        private ILogger _logger = new Logger();
        private readonly Stopwatch _stopwatch = new Stopwatch();

        public override void ScalarExecuting(DbCommand command, DbCommandInterceptionContext<object>
interceptionContext)
        {
            base.ScalarExecuting(command, interceptionContext);
            _stopwatch.Restart();
        }

        public override void ScalarExecuted(DbCommand command, DbCommandInterceptionContext<object>
```

```
        public override void ScalarExecuted(DbCommand command, DbCommandInterceptionContext<object>
interceptionContext)
        {
            _stopwatch.Stop();
            if (interceptionContext.Exception != null)
            {
                _logger.Error(interceptionContext.Exception, "Error executing command: {0}",
command.CommandText);
            }
            else
            {
                _logger.TraceApi("SQL Database", "SchoolInterceptor.ScalarExecuted",
_stopwatch.Elapsed, "Command: {0}: ", command.CommandText);
            }
            base.ScalarExecuted(command, interceptionContext);
        }

        public override void NonQueryExecuting(DbCommand command, DbCommandInterceptionContext<int>
interceptionContext)
        {
            base.NonQueryExecuting(command, interceptionContext);
            _stopwatch.Restart();
        }

        public override void NonQueryExecuted(DbCommand command, DbCommandInterceptionContext<int>
interceptionContext)
        {
            _stopwatch.Stop();
            if (interceptionContext.Exception != null)
            {
                _logger.Error(interceptionContext.Exception, "Error executing command: {0}",
command.CommandText);
            }
            else
            {
                _logger.TraceApi("SQL Database", "SchoolInterceptor.NonQueryExecuted",
_stopwatch.Elapsed, "Command: {0}: ", command.CommandText);
            }
            base.NonQueryExecuted(command, interceptionContext);
        }

        public override void ReaderExecuting(DbCommand command,
DbCommandInterceptionContext<DbDataReader> interceptionContext)
        {
            base.ReaderExecuting(command, interceptionContext);
            _stopwatch.Restart();
        }
        public override void ReaderExecuted(DbCommand command,
DbCommandInterceptionContext<DbDataReader> interceptionContext)
        {
            _stopwatch.Stop();
            if (interceptionContext.Exception != null)
            {
                _logger.Error(interceptionContext.Exception, "Error executing command: {0}",
command.CommandText);
            }
            else
            {
                _logger.TraceApi("SQL Database", "SchoolInterceptor.ReaderExecuted",
_stopwatch.Elapsed, "Command: {0}: ", command.CommandText);
            }
            base.ReaderExecuted(command, interceptionContext);
        }
    }
}
```

For successful queries or commands, this code writes an Information log with latency information. For exceptions, it creates an Error log.

2. To create the interceptor class that will generate dummy transient errors when you enter "Throw" in the **Search** box, create a class file named *SchoolInterceptorTransientErrors.cs* in the *DAL* folder, and replace the template code with the following code:

```
using System;
using System.Data.Common;
using System.Data.Entity;
using System.Data.Entity.Infrastructure.Interception;
using System.Data.Entity.SqlServer;
using System.Data.SqlClient;
using System.Diagnostics;
using System.Reflection;
using System.Linq;
using ContosoUniversity.Logging;

namespace ContosoUniversity.DAL
{
    public class SchoolInterceptorTransientErrors : DbCommandInterceptor
    {
        private int _counter = 0;
        private ILogger _logger = new Logger();

        public override void ReaderExecuting(DbCommand command,
DbCommandInterceptionContext<DbDataReader> interceptionContext)
        {
            bool throwTransientErrors = false;
            if (command.Parameters.Count > 0 && command.Parameters[0].Value.ToString() == "%Throw%")
            {
                throwTransientErrors = true;
                command.Parameters[0].Value = "%an%";
                command.Parameters[1].Value = "%an%";
            }

            if (throwTransientErrors && _counter < 4)
            {
                _logger.Information("Returning transient error for command: {0}", command.CommandText);
                _counter++;
                interceptionContext.Exception = CreateDummySqlException();
            }
        }

        private SqlException CreateDummySqlException()
        {
            // The instance of SQL Server you attempted to connect to does not support encryption
            var sqlErrorNumber = 20;

            var sqlErrorCtor = typeof(SqlError).GetConstructors(BindingFlags.Instance |
BindingFlags.NonPublic).Where(c => c.GetParameters().Count() == 7).Single();
            var sqlError = sqlErrorCtor.Invoke(new object[] { sqlErrorNumber, (byte)0, (byte)0, "", "",
"", 1 });

            var errorCollection = Activator.CreateInstance(typeof(SqlErrorCollection), true);
            var addMethod = typeof(SqlErrorCollection).GetMethod("Add", BindingFlags.Instance |
BindingFlags.NonPublic);
            addMethod.Invoke(errorCollection, new[] { sqlError });

            var sqlExceptionCtor = typeof(SqlException).GetConstructors(BindingFlags.Instance |
BindingFlags.NonPublic).Where(c => c.GetParameters().Count() == 4).Single();
            var sqlException = (SqlException)sqlExceptionCtor.Invoke(new object[] { "Dummy",
errorCollection, null, Guid.NewGuid() });

            return sqlException;
        }
    }
}
```

This code only overrides the `ReaderExecuting` method, which is called for queries that can return multiple rows of data. If you wanted to check connection resiliency for other types of queries, you could also override the `NonQueryExecuting` and `ScalarExecuting` methods, as the logging interceptor does.

When you run the Student page and enter "Throw" as the search string, this code creates a dummy SQL Database exception for error number 20, a type known to be typically transient. Other error numbers currently recognized as transient are 64, 233, 10053, 10054, 10060, 10928, 10929, 40197, 40501, and 40613, but these are subject to change in new versions of SQL Database.

The code returns the exception to Entity Framework instead of running the query and passing back query results. The transient exception is returned four times, and then the code reverts to the normal procedure of passing the query to the database.

Because everything is logged, you'll be able to see that Entity Framework tries to execute the query four times before finally succeeding, and the only difference in the application is that it takes longer to render a page with query results.

The number of times the Entity Framework will retry is configurable; the code specifies four times because that's the default value for the SQL Database execution policy. If you change the execution policy, you'd also change the code here that specifies how many times transient errors are generated. You could also change the code to generate more exceptions so that Entity Framework will throw the `RetryLimitExceededException` exception.

The value you enter in the Search box will be in `command.Parameters[0]` and `command.Parameters[1]` (one is used for the first name and one for the last name). When the value "%Throw%" is found, "Throw" is replaced in those parameters by "an" so that some students will be found and returned.

This is just a convenient way to test connection resiliency based on changing some input to the application UI. You can also write code that generates transient errors for all queries or updates, as explained later in the comments about the *DbInterception.Add* method.

3. In *Global.asax*, add the following `using` statements:

```
using ContosoUniversity.DAL;
using System.Data.Entity.Infrastructure.Interception;
```

4. Add the highlighted lines to the `Application_Start` method:

```
protected void Application_Start()
{
    AreaRegistration.RegisterAllAreas();
    FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
    RouteConfig.RegisterRoutes(RouteTable.Routes);
    BundleConfig.RegisterBundles(BundleTable.Bundles);
    DbInterception.Add(new SchoolInterceptorTransientErrors());
    DbInterception.Add(new SchoolInterceptorLogging());
}
```

These lines of code are what causes your interceptor code to be run when Entity Framework sends queries to the database. Notice that because you created separate interceptor classes for transient error simulation and logging, you can independently enable and disable them.

You can add interceptors using the `DbInterception.Add` method anywhere in your code; it doesn't have to be in the `Application_Start` method. Another option is to put this code in the DbConfiguration class that you created earlier to configure the execution policy.

```
public class SchoolConfiguration : DbConfiguration
{
    public SchoolConfiguration()
    {
        SetExecutionStrategy("System.Data.SqlClient", () => new SqlAzureExecutionStrategy());
        DbInterception.Add(new SchoolInterceptorTransientErrors());
        DbInterception.Add(new SchoolInterceptorLogging());
    }
}
```

Wherever you put this code, be careful not to execute `DbInterception.Add` for the same interceptor more than once, or you'll get additional interceptor instances. For example, if you add the logging interceptor twice, you'll see two logs for every SQL query.

Interceptors are executed in the order of registration (the order in which the `DbInterception.Add` method is called). The order might matter depending on what you're doing in the interceptor. For example, an interceptor might change the SQL command that it gets in the `CommandText` property. If it does change the SQL command, the next interceptor will get the changed SQL command, not the original SQL command.

You've written the transient error simulation code in a way that lets you cause transient errors by entering a different value in the UI. As an alternative, you could write the interceptor code to always generate the sequence of transient exceptions without checking for a particular parameter value. You could then add the interceptor only when you want to generate transient errors. If you do this, however, don't add the interceptor until after database initialization has completed. In other words, do at least one database operation such as a query on one of your entity sets before you start generating transient errors. The Entity Framework executes several queries during database initialization, and they aren't executed in a transaction, so errors during initialization could cause the context to get into an inconsistent state.

Test the new configuration

1. Press **F5** to run the application in debug mode, and then click the **Students** tab.

2. Look at the Visual Studio **Output** window to see the tracing output. You might have to scroll up past some JavaScript errors to get to the logs written by your logger.

   Notice that you can see the actual SQL queries sent to the database. You see some initial queries and commands that Entity Framework does to get started, checking the database version and migration history table (you'll learn about migrations in the next tutorial). And you see a query for paging, to find out how many students there are, and finally you see the query that gets the student data.

```

    ORDER BY [Extent1].[LastName] ASC:
```

3. In the **Students** page, enter "Throw" as the search string, and click **Search**.

You'll notice that the browser seems to hang for several seconds while Entity Framework is retrying the query several times. The first retry happens very quickly, then the wait before increases before each additional retry. This process of waiting longer before each retry is called *exponential backoff*.

When the page displays, showing students who have "an" in their names, look at the output window, and you'll see that the same query was attempted five times, the first four times returning transient exceptions. For each transient error you'll see the log that you write when generating the transient error in the `SchoolInterceptorTransientErrors` class ("Returning transient error for command...") and you'll see the log written when `SchoolInterceptorLogging` gets the exception.

```
Output

ClientConnectionId:bf3d3750-18e6-4e20-9ce7-a31ccd41d74b
```

Since you entered a search string, the query that returns student data is parameterized:

```
SELECT TOP (3)
    [Project1].[ID] AS [ID],
    [Project1].[LastName] AS [LastName],
    [Project1].[FirstMidName] AS [FirstMidName],
    [Project1].[EnrollmentDate] AS [EnrollmentDate]
    FROM ( SELECT [Project1].[ID] AS [ID], [Project1].[LastName] AS [LastName], [Project1].
[FirstMidName] AS [FirstMidName], [Project1].[EnrollmentDate] AS [EnrollmentDate], row_number() OVER
(ORDER BY [Project1].[LastName] ASC) AS [row_number]
        FROM ( SELECT
            [Extent1].[ID] AS [ID],
            [Extent1].[LastName] AS [LastName],
            [Extent1].[FirstMidName] AS [FirstMidName],
            [Extent1].[EnrollmentDate] AS [EnrollmentDate]
            FROM [dbo].[Student] AS [Extent1]
            WHERE ([Extent1].[LastName] LIKE @p__linq__0 ESCAPE N'~') OR ([Extent1].[FirstMidName] LIKE
@p__linq__1 ESCAPE N'~')
        )  AS [Project1]
    )  AS [Project1]
    WHERE [Project1].[row_number] > 0
    ORDER BY [Project1].[LastName] ASC:
```

You're not logging the value of the parameters, but you could do that. If you want to see the parameter values, you can write logging code to get parameter values from the `Parameters` property of the `DbCommand` object that you get in the interceptor methods.

Note that you can't repeat this test unless you stop the application and restart it. If you wanted to be able to test connection resiliency multiple times in a single run of the application, you could write code to reset the error counter in `SchoolInterceptorTransientErrors`.

4. To see the difference the execution strategy (retry policy) makes, comment out the `SetExecutionStrategy` line in *SchoolConfiguration.cs*, run the Students page in debug mode again, and search for "Throw" again.

   This time the debugger stops on the first generated exception immediately when it tries to execute the query the first time.

5. Uncomment the *SetExecutionStrategy* line in *SchoolConfiguration.cs*.

Get the code

Download Completed Project

Additional resources

Links to other Entity Framework resources can be found in ASP.NET Data Access - Recommended Resources.

Next steps

In this tutorial, you:

- Enabled connection resiliency
- Enabled command interception
- Tested the new configuration

Advance to the next article to learn about Code First migrations and Azure deployment.

Code First migrations and Azure deployment

Tutorial: Use EF Migrations in an ASP.NET MVC app and deploy to Azure

9/16/2020 • 20 minutes to read • Edit Online

So far the Contoso University sample web application has been running locally in IIS Express on your development computer. To make a real application available for other people to use over the Internet, you have to deploy it to a web hosting provider. In this tutorial, you enable Code First migrations and deploy the application to the cloud in Azure:

- Enable Code First Migrations. The Migrations feature enables you to change the data model and deploy your changes to production by updating the database schema without having to drop and re-create the database.
- Deploy to Azure. This step is optional; you can continue with the remaining tutorials without having deployed the project.

We recommend that you use a continuous integration process with source control for deployment, but this tutorial does not cover those topics. For more information, see the source control and continuous integration chapters of Building Real-World Cloud Apps with Azure.

In this tutorial, you:

- Enable Code First migrations
- Deploy the app in Azure (optional)

Prerequisites

- Connection Resiliency and Command Interception

Enable Code First migrations

When you develop a new application, your data model changes frequently, and each time the model changes, it gets out of sync with the database. You have configured the Entity Framework to automatically drop and re-create the database each time you change the data model. When you add, remove, or change entity classes or change your `DbContext` class, the next time you run the application it automatically deletes your existing database, creates a new one that matches the model, and seeds it with test data.

This method of keeping the database in sync with the data model works well until you deploy the application to production. When the application is running in production, it is usually storing data that you want to keep, and you don't want to lose everything each time you make a change such as adding a new column. The Code First Migrations feature solves this problem by enabling Code First to update the database schema instead of dropping and re-creating the database. In this tutorial, you'll deploy the application, and to prepare for that you'll enable Migrations.

1. Disable the initializer that you set up earlier by commenting out or deleting the `contexts` element that you added to the application Web.config file.

```
<entityFramework>
  <!--<contexts>
    <context type="ContosoUniversity.DAL.SchoolContext, ContosoUniversity">
      <databaseInitializer type="ContosoUniversity.DAL.SchoolInitializer, ContosoUniversity" />
    </context>
  </contexts>-->
  <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFactory,
EntityFramework">
    <parameters>
      <parameter value="v11.0" />
    </parameters>
  </defaultConnectionFactory>
  <providers>
    <provider invariantName="System.Data.SqlClient"
type="System.Data.Entity.SqlServer.SqlProviderServices, EntityFramework.SqlServer" />
  </providers>
</entityFramework>
```

2. Also in the application *Web.config* file, change the name of the database in the connection string to ContosoUniversity2.

```
<connectionStrings>
  <add name="SchoolContext" connectionString="Data Source=(LocalDb)\MSSQLLocalDB;Initial
Catalog=ContosoUniversity2;Integrated Security=SSPI;" providerName="System.Data.SqlClient" />
</connectionStrings>
```

   This change sets up the project so that the first migration creates a new database. This isn't required but you'll see later why it's a good idea.

3. From the **Tools** menu, select **NuGet Package Manager** > **Package Manager Console**.

4. At the `PM>` prompt enter the following commands:

```
enable-migrations
add-migration InitialCreate
```

   The `enable-migrations` command creates a *Migrations* folder in the ContosoUniversity project, and it puts in that folder a *Configuration.cs* file that you can edit to configure Migrations.

   (If you missed the step above that directs you to change the database name, Migrations will find the existing database and automatically do the `add-migration` command. That's okay, it just means you won't run a test of the migrations code before you deploy the database. Later when you run the `update-database` command nothing will happen because the database already exists.)

   Open the *ContosoUniversity\Migrations\Configuration.cs* file. Like the initializer class that you saw earlier, the `Configuration` class includes a `Seed` method.

```
internal sealed class Configuration : DbMigrationsConfiguration<ContosoUniversity.DAL.SchoolContext>
{
    public Configuration()
    {
        AutomaticMigrationsEnabled = false;
    }

    protected override void Seed(ContosoUniversity.DAL.SchoolContext context)
    {
        //  This method will be called after migrating to the latest version.

        //  You can use the DbSet<T>.AddOrUpdate() helper extension method
        //  to avoid creating duplicate seed data. E.g.
        //
        //    context.People.AddOrUpdate(
        //      p => p.FullName,
        //      new Person { FullName = "Andrew Peters" },
        //      new Person { FullName = "Brice Lambson" },
        //      new Person { FullName = "Rowan Miller" }
        //    );
        //
    }
}
```

The purpose of the Seed method is to enable you to insert or update test data after Code First creates or updates the database. The method is called when the database is created and every time the database schema is updated after a data model change.

Set up the Seed method

When you drop and re-create the database for every data model change, you use the initializer class's `Seed` method to insert test data, because after every model change the database is dropped and all the test data is lost. With Code First Migrations, test data is retained after database changes, so including test data in the Seed method is typically not necessary. In fact, you don't want the `Seed` method to insert test data if you'll be using Migrations to deploy the database to production, because the `Seed` method will run in production. In that case, you want the `Seed` method to insert into the database only the data that you need in production. For example, you might want the database to include actual department names in the `Department` table when the application becomes available in production.

For this tutorial, you'll be using Migrations for deployment, but your `Seed` method will insert test data anyway in order to make it easier to see how application functionality works without having to manually insert a lot of data.

1. Replace the contents of the *Configuration.cs* file with the following code, which loads test data into the new database.

```
namespace ContosoUniversity.Migrations
{
    using ContosoUniversity.Models;
    using System;
    using System.Collections.Generic;
    using System.Data.Entity;
    using System.Data.Entity.Migrations;
    using System.Linq;

    internal sealed class Configuration :
DbMigrationsConfiguration<ContosoUniversity.DAL.SchoolContext>
    {
        public Configuration()
        {
            AutomaticMigrationsEnabled = false;
        }

        protected override void Seed(ContosoUniversity.DAL.SchoolContext context)
```

```
        protected override void Seed(ContosoUniversity.DAL.SchoolContext context)
        {
            var students = new List<Student>
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-08-11") }
            };
            students.ForEach(s => context.Students.AddOrUpdate(p => p.LastName, s));
            context.SaveChanges();

            var courses = new List<Course>
            {
                new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3, },
                new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3, },
                new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3, },
                new Course {CourseID = 1045, Title = "Calculus",       Credits = 4, },
                new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4, },
                new Course {CourseID = 2021, Title = "Composition",    Credits = 3, },
                new Course {CourseID = 2042, Title = "Literature",     Credits = 4, }
            };
            courses.ForEach(s => context.Courses.AddOrUpdate(p => p.Title, s));
            context.SaveChanges();

            var enrollments = new List<Enrollment>
            {
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alexander").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
                    Grade = Grade.A
                },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alexander").ID,
                    CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
                    Grade = Grade.C
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alexander").ID,
                    CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                     StudentID = students.Single(s => s.LastName == "Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                     StudentID = students.Single(s => s.LastName == "Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
                    Grade = Grade.B
                 },
```

```
                new Enrollment {
                   StudentID = students.Single(s => s.LastName == "Anand").ID,
                   CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
                },
                new Enrollment {
                   StudentID = students.Single(s => s.LastName == "Anand").ID,
                   CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
                   Grade = Grade.B
                },
               new Enrollment {
                   StudentID = students.Single(s => s.LastName == "Barzdukas").ID,
                   CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                   Grade = Grade.B
                },
                new Enrollment {
                   StudentID = students.Single(s => s.LastName == "Li").ID,
                   CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                   Grade = Grade.B
                },
                new Enrollment {
                   StudentID = students.Single(s => s.LastName == "Justice").ID,
                   CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                   Grade = Grade.B
                }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                         s.Student.ID == e.StudentID &&
                         s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

The Seed method takes the database context object as an input parameter, and the code in the method uses that object to add new entities to the database. For each entity type, the code creates a collection of new entities, adds them to the appropriate DbSet property, and then saves the changes to the database. It isn't necessary to call the SaveChanges method after each group of entities, as is done here, but doing that helps you locate the source of a problem if an exception occurs while the code is writing to the database.

Some of the statements that insert data use the AddOrUpdate method to perform an "upsert" operation. Because the `Seed` method runs every time you execute the `update-database` command, typically after each migration, you can't just insert data, because the rows you are trying to add will already be there after the first migration that creates the database. The "upsert" operation prevents errors that would happen if you try to insert a row that already exists, but it ***overrides*** any changes to data that you may have made while testing the application. With test data in some tables you might not want that to happen: in some cases when you change data while testing you want your changes to remain after database updates. In that case you want to do a conditional insert operation: insert a row only if it doesn't already exist. The Seed method uses both approaches.

The first parameter passed to the AddOrUpdate method specifies the property to use to check if a row already exists. For the test student data that you are providing, the `LastName` property can be used for this purpose since each last name in the list is unique:

```
context.Students.AddOrUpdate(p => p.LastName, s)
```

This code assumes that last names are unique. If you manually add a student with a duplicate last name, you'll get the following exception the next time you perform a migration:

```
Sequence contains more than one element
```

For information about how to handle redundant data such as two students named "Alexander Carson", see Seeding and Debugging Entity Framework (EF) DBs on Rick Anderson's blog. For more information about the `AddOrUpdate` method, see Take care with EF 4.3 AddOrUpdate Method on Julie Lerman's blog.

The code that creates `Enrollment` entities assumes you have the `ID` value in the entities in the `students` collection, although you didn't set that property in the code that creates the collection.

```
new Enrollment {
    StudentID = students.Single(s => s.LastName == "Alexander").ID,
    CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
    Grade = Grade.A
},
```

You can use the `ID` property here because the `ID` value is set when you call `SaveChanges` for the `students` collection. EF automatically gets the primary key value when it inserts an entity into the database, and it updates the `ID` property of the entity in memory.

The code that adds each `Enrollment` entity to the `Enrollments` entity set doesn't use the `AddOrUpdate` method. It checks if an entity already exists and inserts the entity if it doesn't exist. This approach will preserve changes you make to an enrollment grade by using the application UI. The code loops through each member of the `Enrollment` List and if the enrollment is not found in the database, it adds the enrollment to the database. The first time you update the database, the database will be empty, so it will add each enrollment.

```
foreach (Enrollment e in enrollments)
{
    var enrollmentInDataBase = context.Enrollments.Where(
        s => s.Student.ID == e.Student.ID &&
             s.Course.CourseID == e.Course.CourseID).SingleOrDefault();
    if (enrollmentInDataBase == null)
    {
        context.Enrollments.Add(e);
    }
}
```

2. Build the project.

Execute the first migration

When you executed the `add-migration` command, Migrations generated the code that would create the database from scratch. This code is also in the *Migrations* folder, in the file named *<timestamp>_InitialCreate.cs*. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them.

```
public partial class InitialCreate : DbMigration
{
    public override void Up()
    {
        CreateTable(
            "dbo.Course",
            c => new
                {
                    CourseID = c.Int(nullable: false),
                    Title = c.String(),
                    Credits = c.Int(nullable: false),
                })
            .PrimaryKey(t => t.CourseID);

        CreateTable(
            "dbo.Enrollment",
            c => new
                {
                    EnrollmentID = c.Int(nullable: false, identity: true),
                    CourseID = c.Int(nullable: false),
                    StudentID = c.Int(nullable: false),
                    Grade = c.Int(),
                })
            .PrimaryKey(t => t.EnrollmentID)
            .ForeignKey("dbo.Course", t => t.CourseID, cascadeDelete: true)
            .ForeignKey("dbo.Student", t => t.StudentID, cascadeDelete: true)
            .Index(t => t.CourseID)
            .Index(t => t.StudentID);

        CreateTable(
            "dbo.Student",
            c => new
                {
                    ID = c.Int(nullable: false, identity: true),
                    LastName = c.String(),
                    FirstMidName = c.String(),
                    EnrollmentDate = c.DateTime(nullable: false),
                })
            .PrimaryKey(t => t.ID);

    }

    public override void Down()
    {
        DropForeignKey("dbo.Enrollment", "StudentID", "dbo.Student");
        DropForeignKey("dbo.Enrollment", "CourseID", "dbo.Course");
        DropIndex("dbo.Enrollment", new[] { "StudentID" });
        DropIndex("dbo.Enrollment", new[] { "CourseID" });
        DropTable("dbo.Student");
        DropTable("dbo.Enrollment");
        DropTable("dbo.Course");
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method.

This is the initial migration that was created when you entered the `add-migration InitialCreate` command. The parameter (`InitialCreate` in the example) is used for the file name and can be whatever you want; you typically choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

If you created the initial migration when the database already exists, the database creation code is generated but it doesn't have to run because the database already matches the data model. When you deploy the app to another

environment where the database doesn't exist yet, this code will run to create your database, so it's a good idea to test it first. That's why you changed the name of the database in the connection string earlier—so that migrations can create a new one from scratch.

1. In the **Package Manager Console** window, enter the following command:

   ```
   update-database
   ```

   The `update-database` command runs the `Up` method to create the database and then it runs the `Seed` method to populate the database. The same process will run automatically in production after you deploy the application, as you'll see in the following section.

2. Use **Server Explorer** to inspect the database as you did in the first tutorial, and run the application to verify that everything still works the same as before.

Deploy to Azure

So far the application has been running locally in IIS Express on your development computer. To make it available for other people to use over the Internet, you have to deploy it to a web hosting provider. In this section of the tutorial, you'll deploy it to Azure. This section is optional; you can skip this and continue with the following tutorial, or you can adapt the instructions in this section for a different hosting provider of your choice.

Use Code First migrations to deploy the database

To deploy the database, you'll use Code First Migrations. When you create the publish profile that you use to configure settings for deploying from Visual Studio, you'll select a check box labeled **Update Database**. This setting causes the deployment process to automatically configure the application *Web.config* file on the destination server so that Code First uses the `MigrateDatabaseToLatestVersion` initializer class.

Visual Studio doesn't do anything with the database during the deployment process while it is copying your project to the destination server. When you run the deployed application and it accesses the database for the first time after deployment, Code First checks if the database matches the data model. If there's a mismatch, Code First automatically creates the database (if it doesn't exist yet) or updates the database schema to the latest version (if a database exists but doesn't match the model). If the application implements a Migrations `Seed` method, the method runs after the database is created or the schema is updated.

Your Migrations `Seed` method inserts test data. If you were deploying to a production environment, you would have to change the `Seed` method so that it only inserts data that you want to be inserted into your production database. For example, in your current data model you might want to have real courses but fictional students in the development database. You can write a `Seed` method to load both in development, and then comment out the fictional students before you deploy to production. Or you can write a `Seed` method to load only courses, and enter the fictional students in the test database manually by using the application's UI.

Get an Azure account

You'll need an Azure account. If you don't already have one, but you do have a Visual Studio subscription, you can activate your subscription benefits. Otherwise, you can create a free trial account in just a couple of minutes. For details, see Azure Free Trial.

Create a web site and a SQL database in Azure

Your web app in Azure will run in a shared hosting environment, which means it runs on virtual machines (VMs) that are shared with other Azure clients. A shared hosting environment is a low-cost way to get started in the cloud. Later, if your web traffic increases, the application can scale to meet the need by running on dedicated VMs. To learn more about Pricing Options for Azure App Service, read App Service pricing.

You'll deploy the database to Azure SQL database. SQL database is a cloud-based relational database service that is built on SQL Server technologies. Tools and applications that work with SQL Server also work with SQL database.

1. In the Azure Management Portal, choose **Create a resource** in the left tab and then choose **See all** on the **New** pane (or *blade*) to see all available resources. Choose **Web App + SQL** in the **Web** section of the **Everything** blade. Finally, choose **Create**.

The form to create a new **New Web App + SQL** resource opens.

2. Enter a string in the **App name** box to use as the unique URL for your application. The complete URL will consist of what you enter here plus the default domain of Azure App Services (.azurewebsites.net). If the **App name** is already taken, the Wizard notifies you with a red *The app name is not available* message. If the **App name** is available, you see a green checkmark.

3. In the **Subscription** box, choose the Azure Subscription in which you want the **App Service** to reside.

4. In the **Resource Group** text box, choose a Resource Group or create a new one. This setting specifies which data center your web site will run in. For more information about Resource Groups, see Resource groups.

5. Create a new **App Service Plan** by clicking the *App Service section*, **Create New**, and fill in **App Service plan** (can be same name as App Service), **Location**, and **Pricing tier** (there is a free option).

6. Click **SQL Database**, and then choose **Create a new database** or select an existing database.

7. In the **Name** box, enter a name for your database.

8. Click the **Target Server** box, and then select **Create a new server**. Alternatively, if you previously created a server, you can select that server from list of available servers.

9. Choose **Pricing tier** section, choose *Free*. If additional resources are needed, the database can be scaled up at any time. To learn more on Azure SQL Pricing, see Azure SQL Database pricing.

10. Modify collation as needed.

11. Enter an administrator **SQL Admin Username** and **SQL Admin Password**.

    - If you selected **New SQL Database server**, define a new name and password that you'll use later when you access the database.
    - If you selected a server that you created previously, enter credentials for that server.

12. Telemetry collection can be enabled for App Service using Application Insights. With little configuration, Application Insights collects valuable event, exception, dependency, request, and trace information. To learn more about Application Insights, see Azure Monitor.

13. Click **Create** at the bottom to indicate that you're finished.

The Management Portal returns to the Dashboard page, and the **Notifications** area at the top of the page shows that the site is being created. After a while (typically less than a minute), there's a notification that the Deployment succeeded. In the navigation bar at the left, the new App Service appears in the **App Services** section and the new SQL database appears in the **SQL databases** section.

Deploy the app to Azure

1. In Visual Studio, right-click the project in **Solution Explorer** and select **Publish** from the context menu.

2. On the **Pick a publish target** page, choose **App Service** and then **Select Existing**, and then choose **Publish**.

3. If you haven't previously added your Azure subscription in Visual Studio, perform the steps on the screen. These steps enable Visual Studio to connect to your Azure subscription so that the list of **App Services** will include your web site.

4. On the **App Service** page, select the **Subscription** you added the App Service to. Under **View**, select **Resource Group**. Expand the resource group you added the App Service to, and then select the App Service. Choose **OK** to publish the app.

5. The **Output** window shows what deployment actions were taken and reports successful completion of the deployment.

6. Upon successful deployment, the default browser automatically opens to the URL of the deployed web site.

Your app is now running in the cloud.

At this point, the *SchoolContext* database has been created in the Azure SQL database because you selected **Execute Code First Migrations (runs on app start)**. The *Web.config* file in the deployed web site has been changed so that the MigrateDatabaseToLatestVersion initializer runs the first time your code reads or writes data in the database (which happened when you selected the **Students** tab):

```
</runtime>
  <entityFramework>
    <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFa
      <parameters>
        <parameter value="v11.0" />
      </parameters>
    </defaultConnectionFactory>
    <contexts>
      <context type="ContosoUniversity.Models.SchoolContext, ContosoUniversity">
        <databaseInitializer type="System.Data.Entity.MigrateDatabaseToLatestVersion`2[
                              [ContosoUniversity.Models.SchoolContext, ContosoUniversity],
                              [ContosoUniversity.Migrations.Configuration, ContosoUniversi
                              EntityFramework, PublicKeyToken=b77a5c561934e089">
          <parameters>
            <parameter value="SchoolContext_DatabasePublish"/>
          </parameters>
        </databaseInitializer>
      </context>
    </contexts>
  </entityFramework>
</configuration>
```

The deployment process also created a new connection string *(SchoolContext_DatabasePublish)* for Code First Migrations to use for updating the database schema and seeding the database.

```
<connectionStrings>
    <add name="SchoolContext" connectionString="Data Source=tcp:d015leqjqx.database.winc
    <add name="SchoolContext_DatabasePublish" connectionString="Data Source=tcp:d015leq
</connectionStrings>
```

You can find the deployed version of the Web.config file on your own computer in *ContosoUniversity\obj\Release\Package\PackageTmp\Web.config*. You can access the deployed *Web.config* file itself by using FTP. For instructions, see ASP.NET Web Deployment using Visual Studio: Deploying a Code Update. Follow the instructions that start with "To use an FTP tool, you need three things: the FTP URL, the user name, and the password."

> **NOTE**
> The web app doesn't implement security, so anyone who finds the URL can change the data. For instructions on how to secure the web site, see Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL database to Azure. You can prevent other people from using the site by stopping the service using the Azure Management Portal or **Server Explorer** in Visual Studio.

Advanced migrations scenarios

If you deploy a database by running migrations automatically as shown in this tutorial, and you are deploying to a web site that runs on multiple servers, you could get multiple servers trying to run migrations at the same time. Migrations are atomic, so if two servers try to run the same migration, one will succeed and the other will fail (assuming the operations can't be done twice). In that scenario if you want to avoid those issues, you can call migrations manually and set up your own code so that it only happens once. For more information, see Running and Scripting Migrations from Code on Rowan Miller's blog and Migrate.exe (for executing migrations from the command line).

For information about other migrations scenarios, see Migrations Screencast Series.

Update specific migration

```
update-database -target MigrationName
```

The `update-database -target MigrationName` command runs the targeted migration.

Ignore migration changes to database

```
Add-migration MigrationName -ignoreChanges
```

`ignoreChanges` creates an empty migration with the current model as a snapshot.

Code First initializers

In the deployment section, you saw the MigrateDatabaseToLatestVersion initializer being used. Code First also provides other initializers, including CreateDatabaseIfNotExists (the default), DropCreateDatabaseIfModelChanges (which you used earlier) and DropCreateDatabaseAlways. The `DropCreateAlways` initializer can be useful for setting up conditions for unit tests. You can also write your own initializers, and you can call an initializer explicitly if you

don't want to wait until the application reads from or writes to the database.

For more information about initializers, see Understanding Database Initializers in Entity Framework Code First and chapter 6 of the book Programming Entity Framework: Code First by Julie Lerman and Rowan Miller.

Links to other Entity Framework resources can be found in ASP.NET Data Access - Recommended Resources.

Next steps

In this tutorial, you:

- Enabled Code First migrations
- Deployed the app in Azure (optional)

Advance to the next article to learn how to create a more complex data model for an ASP.NET MVC Application.

Create a more complex data model

Tutorial: Create a more complex data model for an ASP.NET MVC app

2/20/2020 • 32 minutes to read • Edit Online

In the previous tutorials you worked with a simple data model that was composed of three entities. In this tutorial you add more entities and relationships and you customize the data model by specifying formatting, validation, and database mapping rules. This article shows two ways to customize the data model: by adding attributes to entity classes and by adding code to the database context class.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:

In this tutorial, you:

- Customize the data model
- Update Student entity
- Create Instructor entity
- Create OfficeAssignment entity

- Modify the Course entity
- Create the Department entity
- Modify the Enrollment entity
- Add code to database context
- Seed database with test data
- Add a migration
- Update the database

Prerequisites

- Code First migrations and deployment

Customize the data model

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete `School` data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType Attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In *Models\Student.cs*, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The DataType attribute is used to specify a data type that is more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The DataType Enumeration provides for many data types, such as *Date, Time, PhoneNumber, Currency, EmailAddress* and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for DataType.EmailAddress, and a date selector can be provided for DataType.Date in browsers that support HTML5. The DataType attributes emits HTML 5 data- (pronounced *data dash*) attributes that HTML 5 browsers can understand. The DataType attributes do not provide any validation.

`DataType.Date` does not specify the format of the date that is displayed. By default, the data field is displayed

according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
```

The `ApplyFormatInEditMode` setting specifies that the specified formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields — for example, for currency values, you might not want the currency symbol in the text box for editing.)

You can use the DisplayFormat attribute by itself, but it's generally a good idea to use the DataType attribute also. The `DataType` attribute conveys the *semantics* of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, some client-side input validation, etc.).
- By default, the browser will render data using the correct format based on your locale.
- The DataType attribute can enable MVC to choose the right field template to render the data (the DisplayFormat uses the string template). For more information, see Brad Wilson's ASP.NET MVC 2 Templates. (Though written for MVC 2, this article still applies to the current version of ASP.NET MVC.)

If you use the `DataType` attribute with a date field, you have to specify the `DisplayFormat` attribute also in order to ensure that the field renders correctly in Chrome browsers. For more information, see this StackOverflow thread.

For more information about how to handle other date formats in MVC, go to MVC 5 Introduction: Examining the Edit Methods and Edit View and search in the page for "internationalization".

Run the Student Index page again and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the `Student` model.

The StringLengthAttribute

You can also specify data validation rules and validation error messages using attributes. The StringLength attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema.

Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add StringLength attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The StringLength attribute won't prevent a user from entering white space for a name. You can use the RegularExpression attribute to apply restrictions to the input. For example the following code requires the first character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z""'\s-]*$")]
```

The MaxLength attribute provides similar functionality to the StringLength attribute but doesn't provide client side validation.

Run the application and click the **Students** tab. You get the following error:

The model backing the 'SchoolContext' context has changed since the database was created. Consider using Code First Migrations to update the database (https://go.microsoft.com/fwlink/?LinkId=238269).

The database model has changed in a way that requires a change in the database schema, and Entity Framework detected that. You'll use migrations to update the schema without losing any data that you added to the database by using the UI. If you changed data that was created by the `Seed` method, that will be changed back to its original state because of the AddOrUpdate method that you're using in the `Seed` method. (AddOrUpdate is equivalent to an "upsert" operation from database terminology.)

In the Package Manager Console (PMC), enter the following commands:

```
add-migration MaxLengthOnNames
update-database
```

The `add-migration` command creates a file named *<timeStamp>_MaxLengthOnNames.cs*. This file contains code in the `Up` method that will update the database to match the current data model. The `update-database` command ran that code.

The timestamp prepended to the migrations file name is used by Entity Framework to order the migrations. You can create multiple migrations before running the `update-database` command, and then all of the migrations are applied in the order in which they were created.

Run the **Create** page, and enter either name longer than 50 characters. When you click **Create**, client side validation shows an error message: *The field LastName must be a string with a maximum length of 50.*

The Column Attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you

had used the name `FirstMidName` for the first-name field because the field might also contain a middle name. But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they are given the same name as the property name.

In the *Student.cs* file, add a `using` statement for System.ComponentModel.DataAnnotations.Schema and add the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]

        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The addition of the Column attribute changes the model backing the SchoolContext, so it won't match the database. Enter the following commands in the PMC to create another migration:

```
add-migration ColumnFirstName
update-database
```

In **Server Explorer**, open the *Student* table designer by double-clicking the *Student* table.

The following image shows the original column name as it was before you applied the first two migrations. In addition to the column name changing from `FirstMidName` to `FirstName`, the two name columns have changed from `MAX` length to 50 characters.

You can also make database mapping changes using the Fluent API, as you'll see later in this tutorial.

> **NOTE**
> If you try to compile before you finish creating all of the entity classes in the following sections, you might get compiler errors.

Update Student entity

In *Models\Student.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required Attribute

The Required attribute makes the name properties required fields. The `Required attribute` is not needed for value types such as DateTime, int, double, and float. Value types cannot be assigned a null value, so they are inherently treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

`MinimumLength` and `Required` allow whitespace to satisfy the validation. Use the `RegularExpression` attribute for full controll over the string.

The Display Attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date" instead of the property name in each instance (which has no space dividing the words).

The FullName Calculated Property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a `get` accessor, and no `FullName` column will be generated in the database.

Create Instructor entity

Create *Models\Instructor.cs*, replacing the template code with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public virtual ICollection<Course> Courses { get; set; }
        public virtual OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the `Student` and `Instructor` entities. In the Implementing Inheritance tutorial later in this series, you'll refactor this code to eliminate the redundancy.

You can put multiple attributes on one line, so you could also write the instructor class as follows:

```
public class Instructor
{
   public int ID { get; set; }

   [Display(Name = "Last Name"),StringLength(50, MinimumLength=1)]
   public string LastName { get; set; }

   [Column("FirstName"),Display(Name = "First Name"),StringLength(50, MinimumLength=1)]
   public string FirstMidName { get; set; }

   [DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
   public DateTime HireDate { get; set; }

   [Display(Name = "Full Name")]
   public string FullName
   {
      get { return LastName + ", " + FirstMidName; }
   }

   public virtual ICollection<Course> Courses { get; set; }
   public virtual OfficeAssignment OfficeAssignment { get; set; }
}
```

The Courses and OfficeAssignment Navigation Properties

The `Courses` and `OfficeAssignment` properties are navigation properties. As was explained earlier, they are typically defined as virtual so that they can take advantage of an Entity Framework feature called lazy loading. In addition, if a navigation property can hold multiple entities, its type must implement the ICollection<T> Interface. For example IList<T> qualifies but not IEnumerable<T> because `IEnumerable<T>` doesn't implement Add.

An instructor can teach any number of courses, so `Courses` is defined as a collection of `Course` entities.

```
public virtual ICollection<Course> Courses { get; set; }
```

Our business rules state an instructor can only have at most one office, so `OfficeAssignment` is defined as a single `OfficeAssignment` entity (which may be `null` if no office is assigned).

```
public virtual OfficeAssignment OfficeAssignment { get; set; }
```

Create OfficeAssignment entity

Create *Models\OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        [ForeignKey("Instructor")]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public virtual Instructor Instructor { get; set; }
    }
}
```

Build the project, which saves your changes and verifies you haven't made any copy and paste errors the compiler can catch.

The Key Attribute

There's a one-to-zero-or-one relationship between the `Instructor` and the `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the `Instructor` entity. But the Entity Framework can't automatically recognize `InstructorID` as the primary key of this entity because its name doesn't follow the `ID` or *classname* `ID` naming convention. Therefore, the `Key` attribute is used to identify it as the key:

```
[Key]
[ForeignKey("Instructor")]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something different than `classnameID` or `ID`. By default EF treats the key as non-database-generated because the column is for an identifying relationship.

The ForeignKey Attribute

When there is a one-to-zero-or-one relationship or a one-to-one relationship between two entities (such as between `OfficeAssignment` and `Instructor`), EF can't work out which end of the relationship is the principal and which end is dependent. One-to-one relationships have a reference navigation property in each class to the other class. The ForeignKey Attribute can be applied to the dependent class to establish the relationship. If you omit the ForeignKey Attribute, you get the following error when you try to create the migration:

Unable to determine the principal end of an association between the types 'ContosoUniversity.Models.OfficeAssignment' and 'ContosoUniversity.Models.Instructor'. The principal end of this association must be explicitly configured using either the relationship fluent API or data annotations.

Later in the tutorial you'll see how to configure this relationship with the fluent API.

The Instructor Navigation Property

The `Instructor` entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the `OfficeAssignment` entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an `Instructor` entity has a related `OfficeAssignment` entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the InstructorID foreign key (which is also the key to this table) is non-nullable.

Modify the Course entity

In *Models\Course.cs*, replace the code you added earlier with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public class Course
   {
      [DatabaseGenerated(DatabaseGeneratedOption.None)]
      [Display(Name = "Number")]
      public int CourseID { get; set; }

      [StringLength(50, MinimumLength = 3)]
      public string Title { get; set; }

      [Range(0, 5)]
      public int Credits { get; set; }

      public int DepartmentID { get; set; }

      public virtual Department Department { get; set; }
      public virtual ICollection<Enrollment> Enrollments { get; set; }
      public virtual ICollection<Instructor> Instructors { get; set; }
   }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related `Department` entity and it has a `Department` navigation property. The Entity Framework doesn't require you to add a foreign key property to your data model when you have a navigation property for a related entity. EF automatically creates foreign keys in the database wherever they are needed. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a course entity to edit, the `Department` entity is null if you don't load it, so when you update the course entity, you would have to first fetch the `Department` entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the `Department` entity before you update.

The DatabaseGenerated Attribute

The DatabaseGenerated attribute with the None parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, the Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for `Course` entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

Foreign Key and Navigation Properties

The foreign key properties and navigation properties in the `Course` entity reflect the following relationships:

- A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

```
public int DepartmentID { get; set; }
public virtual Department Department { get; set; }
```

- A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

```
public virtual ICollection<Enrollment> Enrollments { get; set; }
```

- A course may be taught by multiple instructors, so the `Instructors` navigation property is a collection:

```
public virtual ICollection<Instructor> Instructors { get; set; }
```

Create the Department entity

Create *Models\Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public class Department
   {
      public int DepartmentID { get; set; }

      [StringLength(50, MinimumLength=3)]
      public string Name { get; set; }

      [DataType(DataType.Currency)]
      [Column(TypeName = "money")]
      public decimal Budget { get; set; }

      [DataType(DataType.Date)]
      [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
      [Display(Name = "Start Date")]
      public DateTime StartDate { get; set; }

      public int? InstructorID { get; set; }

      public virtual Instructor Administrator { get; set; }
      public virtual ICollection<Course> Courses { get; set; }
   }
}
```

The Column Attribute

Earlier you used the Column attribute to change column name mapping. In the code for the `Department` entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework usually chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that. For more information about CLR data types and how they match to SQL Server data types, see SqlClient for Entity FrameworkTypes.

Foreign Key and Navigation Properties

The foreign key and navigation properties reflect the following relationships:

- A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the `Instructor` entity, and a question mark is added after the `int` type designation to mark the property as nullable.The navigation property is named `Administrator` but holds an `Instructor` entity:

  ```
  public int? InstructorID { get; set; }
  public virtual Instructor Administrator { get; set; }
  ```

- A department may have many courses, so there's a `Courses` navigation property:

  ```
  public virtual ICollection<Course> Courses { get; set; }
  ```

  > **NOTE**
  >
  > By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when you try to add a migration. For example, if you didn't define the `Department.InstructorID` property as nullable, you'd get the following exception message: "The referential relationship will result in a cyclical reference that's not allowed." If your business rules required `InstructorID` property to be non-nullable, you would have to use the following fluent API statement to disable cascade delete on the relationship:

```
modelBuilder.Entity().HasRequired(d => d.Administrator).WithMany().WillCascadeOnDelete(false);
```

Modify the Enrollment entity

In *Models\Enrollment.cs*, replace the code you added earlier with the following code

```
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public virtual Course Course { get; set; }
        public virtual Student Student { get; set; }
    }
}
```

Foreign Key and Navigation Properties

The foreign key properties and navigation properties reflect the following relationships:

- An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course` navigation property:

  ```
  public int CourseID { get; set; }
  public virtual Course Course { get; set; }
  ```

- An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:

  ```
  public int StudentID { get; set; }
  public virtual Student Student { get; set; }
  ```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities, and the `Enrollment` entity functions as a many-to-many join table *with payload* in the database. This means that the `Enrollment` table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a `Grade` property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)

Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two foreign keys `CourseID` and `StudentID`. In that case, it would correspond to a many-to-many join table *without payload* (or a *pure join table*) in the database, and you wouldn't have to create a model class for it at all. The `Instructor` and `Course` entities have that kind of many-to-many relationship, and as you can see, there is no entity class between them:

A join table is required in the database, however, as shown in the following database diagram:

The Entity Framework automatically creates the `CourseInstructor` table, and you read and update it indirectly by reading and updating the `Instructor.Courses` and `Course.Instructors` navigation properties.

Entity relationship diagram

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.

Besides the many-to-many relationship lines (* to *) and the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Add code to database context

Next you'll add the new entities to the `SchoolContext` class and customize some of the mapping using fluent API calls. The API is "fluent" because it's often used by stringing a series of method calls together into a single statement, as in the following example:

```
modelBuilder.Entity<Course>()
     .HasMany(c => c.Instructors).WithMany(i => i.Courses)
     .Map(t => t.MapLeftKey("CourseID")
         .MapRightKey("InstructorID")
         .ToTable("CourseInstructor"));
```

In this tutorial you'll use the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible.

To add the new entities to the data model and perform database mapping that you didn't do by using attributes, replace the code in *DAL\SchoolContext.cs* with the following code:

```
using ContosoUniversity.Models;
using System.Data.Entity;
using System.Data.Entity.ModelConfiguration.Conventions;

namespace ContosoUniversity.DAL
{
   public class SchoolContext : DbContext
   {
      public DbSet<Course> Courses { get; set; }
      public DbSet<Department> Departments { get; set; }
      public DbSet<Enrollment> Enrollments { get; set; }
      public DbSet<Instructor> Instructors { get; set; }
      public DbSet<Student> Students { get; set; }
      public DbSet<OfficeAssignment> OfficeAssignments { get; set; }

      protected override void OnModelCreating(DbModelBuilder modelBuilder)
      {
         modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();

         modelBuilder.Entity<Course>()
             .HasMany(c => c.Instructors).WithMany(i => i.Courses)
             .Map(t => t.MapLeftKey("CourseID")
                 .MapRightKey("InstructorID")
                 .ToTable("CourseInstructor"));
      }
   }
}
```

The new statement in the OnModelCreating method configures the many-to-many join table:

- For the many-to-many relationship between the `Instructor` and `Course` entities, the code specifies the table and column names for the join table. Code First can configure the many-to-many relationship for you without this code, but if you don't call it, you will get default names such as `InstructorInstructorID` for the `InstructorID` column.

```
modelBuilder.Entity<Course>()
    .HasMany(c => c.Instructors).WithMany(i => i.Courses)
    .Map(t => t.MapLeftKey("CourseID")
        .MapRightKey("InstructorID")
        .ToTable("CourseInstructor"));
```

The following code provides an example of how you could have used fluent API instead of attributes to specify the relationship between the `Instructor` and `OfficeAssignment` entities:

```
modelBuilder.Entity<Instructor>()
    .HasOptional(p => p.OfficeAssignment).WithRequired(p => p.Instructor);
```

For information about what "fluent API" statements are doing behind the scenes, see the Fluent API blog post.

Seed database with test data

Replace the code in the *Migrations\Configuration.cs* file with the following code in order to provide seed data for the new entities you've created.

```
namespace ContosoUniversity.Migrations
{
    using ContosoUniversity.Models;
    using ContosoUniversity.DAL;
    using System;
    using System.Collections.Generic;
    using System.Data.Entity;
    using System.Data.Entity.Migrations;
    using System.Linq;

    internal sealed class Configuration : DbMigrationsConfiguration<SchoolContext>
    {
        public Configuration()
        {
            AutomaticMigrationsEnabled = false;
        }

        protected override void Seed(SchoolContext context)
        {
            var students = new List<Student>
            {
                new Student { FirstMidName = "Carson",   LastName = "Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName = "Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName = "Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName = "Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
```

```
            };

            students.ForEach(s => context.Students.AddOrUpdate(p => p.LastName, s));
            context.SaveChanges();

            var instructors = new List<Instructor>
            {
                new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };
            instructors.ForEach(s => context.Instructors.AddOrUpdate(p => p.LastName, s));
            context.SaveChanges();

            var departments = new List<Department>
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,

                },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").ID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                         s.Student.ID == e.StudentID &&
                         s.Course.CourseID == e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }

        void AddOrUpdateInstructor(SchoolContext context, string courseTitle, string instructorName)
        {
            var crs = context.Courses.SingleOrDefault(c => c.Title == courseTitle);
            var inst = crs.Instructors.SingleOrDefault(i => i.LastName == instructorName);
            if (inst == null)
                crs.Instructors.Add(context.Instructors.Single(i => i.LastName == instructorName));
        }
    }
}
```

As you saw in the first tutorial, most of this code simply updates or creates new entity objects and loads sample data into properties as required for testing. However, notice how the `Course` entity, which has a many-to-many relationship with the `Instructor` entity, is handled:

```
var courses = new List<Course>
{
    new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
      DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID,
      Instructors = new List<Instructor>()
    },
    ...
};
courses.ForEach(s => context.Courses.AddOrUpdate(p => p.CourseID, s));
context.SaveChanges();
```

When you create a `Course` object, you initialize the `Instructors` navigation property as an empty collection using the code `Instructors = new List<Instructor>()`. This makes it possible to add `Instructor` entities that are related to this `Course` by using the `Instructors.Add` method. If you didn't create an empty list, you wouldn't be able to add these relationships, because the `Instructors` property would be null and wouldn't have an `Add` method. You

could also add the list initialization to the constructor.

Add a migration

From the PMC, enter the `add-migration` command (don't do the `update-database` command yet):

`add-Migration ComplexDataModel`

If you tried to run the `update-database` command at this point (don't do it yet), you would get the following error:

The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints, and that's what you have to do now. The generated code in the ComplexDataModel `Up` method adds a non-nullable `DepartmentID` foreign key to the `Course` table. Because there are already rows in the `Course` table when the code runs, the `AddColumn` operation will fail because SQL Server doesn't know what value to put in the column that can't be null. Therefore have to change the code to give the new column a default value, and create a stub department named "Temp" to act as the default department. As a result, existing `Course` rows will all be related to the "Temp" department after the `Up` method runs. You can relate them to the correct departments in the `Seed` method.

Edit the *<timestamp>_ComplexDataModel.cs* file, comment out the line of code that adds the DepartmentID column to the Course table, and add the following highlighted code (the commented line is also highlighted):

```
CreateTable(
        "dbo.CourseInstructor",
        c => new
            {
                CourseID = c.Int(nullable: false),
                InstructorID = c.Int(nullable: false),
            })
        .PrimaryKey(t => new { t.CourseID, t.InstructorID })
        .ForeignKey("dbo.Course", t => t.CourseID, cascadeDelete: true)
        .ForeignKey("dbo.Instructor", t => t.InstructorID, cascadeDelete: true)
        .Index(t => t.CourseID)
        .Index(t => t.InstructorID);

    // Create  a department for course to point to.
    Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00, GETDATE())");
    //  default value for FK points to department created above.
    AddColumn("dbo.Course", "DepartmentID", c => c.Int(nullable: false, defaultValue: 1));
    //AddColumn("dbo.Course", "DepartmentID", c => c.Int(nullable: false));

    AlterColumn("dbo.Course", "Title", c => c.String(maxLength: 50));
```

When the `Seed` method runs, it will insert rows in the `Department` table and it will relate existing `Course` rows to those new `Department` rows. If you haven't added any courses in the UI, you would then no longer need the "Temp" department or the default value on the `Course.DepartmentID` column. To allow for the possibility that someone might have added courses by using the application, you'd also want to update the `Seed` method code to ensure that all `Course` rows (not just the ones inserted by earlier runs of the `Seed` method) have valid `DepartmentID` values before you remove the default value from the column and delete the "Temp" department.

Update the database

After you have finished editing the *<timestamp>_ComplexDataModel.cs* file, enter the `update-database` command in the PMC to execute the migration.

```
update-database
```

NOTE

It's possible to get other errors when migrating data and making schema changes. If you get migration errors you can't resolve, you can either change the database name in the connection string or delete the database. The simplest approach is to rename the database in *Web.config* file. The following example shows the name changed to CU_Test:

```
<add name="SchoolContext" connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=CU_Test;Integrated Security=SSPI;"
      providerName="System.Data.SqlClient" />
```

With a new database, there is no data to migrate, and the `update-database` command is much more likely to complete without errors. For instructions on how to delete the database, see How to Drop a Database from Visual Studio 2012.

If that fails, another thing you can try is re-initialize the database by entering the following command in the PMC:

```
update-database -TargetMigration:0
```

Open the database in **Server Explorer** as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have **Server Explorer** open from the earlier time, click the **Refresh** button.)

You didn't create a model class for the `CourseInstructor` table. As explained earlier, this is a join table for the many-to-many relationship between the `Instructor` and `Course` entities.

Right-click the `CourseInstructor` table and select **Show Table Data** to verify that it has data in it as a result of the `Instructor` entities you added to the `Course.Instructors` navigation property.

dbo.CourseInstructor [Data]

Max Rows: 1000

CourseID	InstructorID
2021	1
2042	1
1045	2
1050	3
3141	3
1050	4
4022	5
4041	5
NULL	NULL

Get the code

Links to other Entity Framework resources can be found in the ASP.NET Data Access - Recommended Resources.

Next steps

In this tutorial, you:

- Customized the data model
- Updated Student entity
- Created Instructor entity
- Created OfficeAssignment entity
- Modified the Course entity
- Created the Department entity
- Modified the Enrollment entity
- Added code to database context
- Seeded database with test data
- Added a migration
- Updated the database

Advance to the next article to learn how to read and display related data that the Entity Framework loads into navigation properties.

Read related data

Tutorial: Read related data with EF in an ASP.NET MVC app

2/20/2020 • 16 minutes to read • Edit Online

In the previous tutorial you completed the School data model. In this tutorial you'll read and display related data — that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.

Download Completed Project

> The Contoso University sample web application demonstrates how to create ASP.NET MVC 5 applications using the Entity Framework 6 Code First and Visual Studio. For information about the tutorial series, see the first tutorial in the series.

In this tutorial, you:

- Learn how to load related data
- Create a Courses page
- Create an Instructors page

Prerequisites

- Create a more complex data model

Learn how to load related data

There are several ways that the Entity Framework can load related data into the navigation properties of an entity:

- *Lazy loading*. When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. This results in multiple queries sent to the database — one for the entity itself and one each time that related data for the entity must be retrieved. The `DbContext` class enables lazy loading by default.

```
departments = context.Departments
foreach (Department d in departments)
{
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- *Eager loading*. When the entity is read, related data is retrieved along with it. This typically results in a single join query that retrieves all of the data that's needed. You specify eager loading by using the `Include` method.

```
departments = context.Departments.Include(x => x.Courses)
foreach (Department d in departments)
{
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows and related Course rows

- *Explicit loading*. This is similar to lazy loading, except that you explicitly retrieve the related data in code; it doesn't happen automatically when you access a navigation property. You load related data manually by getting the object state manager entry for an entity and calling the Collection.Load method for collections or the Reference.Load method for properties that hold a single entity. (In the following example, if you wanted to load the Administrator navigation property, you'd replace `Collection(x => x.Courses)` with `Reference(x => x.Administrator)`.) Typically you'd use explicit loading only when you've turned lazy loading off.

```
departments = context.Departments.ToList();
foreach (Department d in departments)
{
    context.Entry(d).Collection(x => x.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

Because they don't immediately retrieve the property values, lazy loading and explicit loading are also both known as *deferred loading*.

Performance considerations

If you know you need related data for every entity retrieved, eager loading often offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, in the above examples, suppose that each department has ten related courses. The eager loading example would result in just a single (join) query and a single round trip to the database. The lazy loading and explicit loading examples would both result in eleven queries and eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.

On the other hand, in some scenarios lazy loading is more efficient. Eager loading might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of the entities you're processing, lazy loading might perform better because

eager loading would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Lazy loading can mask code that causes performance problems. For example, code that doesn't specify eager or explicit loading but processes a high volume of entities and uses several navigation properties in each iteration might be very inefficient (because of many round trips to the database). An application that performs well in development using an on premise SQL server might have performance problems when moved to Azure SQL Database due to the increased latency and lazy loading. Profiling the database queries with a realistic test load will help you determine if lazy loading is appropriate. For more information see Demystifying Entity Framework Strategies: Loading Related Data and Using the Entity Framework to Reduce Network Latency to SQL Azure.

Disable lazy loading before serialization

If you leave lazy loading enabled during serialization, you can end up querying significantly more data than you intended. Serialization generally works by accessing each property on an instance of a type. Property access triggers lazy loading, and those lazy loaded entities are serialized. The serialization process then accesses each property of the lazy-loaded entities, potentially causing even more lazy loading and serialization. To prevent this run-away chain reaction, turn lazy loading off before you serialize an entity.

Serialization can also be complicated by the proxy classes that the Entity Framework uses, as explained in the Advanced Scenarios tutorial.

One way to avoid serialization problems is to serialize data transfer objects (DTOs) instead of entity objects, as shown in the Using Web API with Entity Framework tutorial.

If you don't use DTOs, you can disable lazy loading and avoid proxy issues by disabling proxy creation.

Here are some other ways to disable lazy loading:

- For specific navigation properties, omit the `virtual` keyword when you declare the property.
- For all navigation properties, set `LazyLoadingEnabled` to `false`, put the following code in the constructor of your context class:

```
this.Configuration.LazyLoadingEnabled = false;
```

Create a Courses page

The `Course` entity includes a navigation property that contains the `Department` entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the `Name` property from the `Department` entity that is in the `Course.Department` navigation property.

Create a controller named `CourseController` (not CoursesController) for the `Course` entity type, using the same options for the **MVC 5 Controller with views, using Entity Framework** scaffolder that you did earlier for the `Student` controller:

SETTING	VALUE
Model class	Select **Course (ContosoUniversity.Models)**.
Data context class	Select **SchoolContext (ContosoUniversity.DAL)**.
Controller name	Enter *CourseController*. Again, not *CoursesController* with an *s*. When you selected **Course (ContosoUniversity.Models)**, the **Controller name** value was automatically populated. You have to change the value.

Leave the other default values and add the controller.

Open *Controllers\CourseController.cs* and look at the `Index` method:

```
public ActionResult Index()
{
    var courses = db.Courses.Include(c => c.Department);
    return View(courses.ToList());
}
```

The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Open *Views\Course\Index.cshtml* and replace the template code with the following code. The changes are highlighted:

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewBag.Title = "Courses";
}

<h2>Courses</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table class="table">
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.CourseID)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Title)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Credits)
        </th>
        <th>
            Department
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.CourseID)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Credits)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Department.Name)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.CourseID }) |
            @Html.ActionLink("Details", "Details", new { id=item.CourseID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.CourseID })
        </td>
    </tr>
}

</table>
```

You've made the following changes to the scaffolded code:

- Changed the heading from **Index** to **Courses**.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they are meaningless to end users. However, in this case the primary key is meaningful and you want to show it.
- Moved the **Department** column to the right side and changed its heading. The scaffolder correctly chose to display the `Name` property from the `Department` entity, but here in the Course page the column heading should be **Department** rather than **Name**.

Notice that for the Department column, the scaffolded code displays the `Name` property of the `Department` entity

that's loaded into the `Department` navigation property:

```
<td>
    @Html.DisplayFor(modelItem => item.Department.Name)
</td>
```

Run the page (select the **Courses** tab on the Contoso University home page) to see the list with department names.

Create an Instructors page

In this section you'll create a controller and view for the `Instructor` entity in order to display the Instructors page. This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity. The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. You'll use eager loading for the `OfficeAssignment` entities. As explained earlier, eager loading is typically more efficient when you need the related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. You'll use eager loading for the `Course` entities and their related `Department` entities. In this case, lazy loading might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity set is displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship. You'll add explicit loading for `Enrollment` entities and their related `Student` entities. (Explicit loading isn't necessary because lazy loading is enabled, but this shows how to do explicit loading.)

Create a View Model for the Instructor Index View

The Instructors page shows three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

In the *ViewModels* folder, create *InstructorIndexData.cs* and replace the existing code with the following code:

```
using System.Collections.Generic;
using ContosoUniversity.Models;

namespace ContosoUniversity.ViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Create the Instructor Controller and Views

Create an `InstructorController` (not InstructorsController) controller with EF read/write action:

SETTING	VALUE
Model class	Select **Instructor (ContosoUniversity.Models)**.

SETTING	VALUE
Data context class	Select **SchoolContext (ContosoUniversity.DAL)**.
Controller name	Enter *InstructorController*. Again, not *InstructorsController* with an *s*. When you selected **Course (ContosoUniversity.Models)**, the **Controller name** value was automatically populated. You have to change the value.

Leave the other default values and add the controller.

Open *Controllers\InstructorController.cs* and add a `using` statement for the `ViewModels` namespace:

```
using ContosoUniversity.ViewModels;
```

The scaffolded code in the `Index` method specifies eager loading only for the `OfficeAssignment` navigation property:

```
public ActionResult Index()
{
    var instructors = db.Instructors.Include(i => i.OfficeAssignment);
    return View(instructors.ToList());
}
```

Replace the `Index` method with the following code to load additional related data and put it in the view model:

```
public ActionResult Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses.Select(c => c.Department))
        .OrderBy(i => i.LastName);

    if (id != null)
    {
        ViewBag.InstructorID = id.Value;
        viewModel.Courses = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single().Courses;
    }

    if (courseID != null)
    {
        ViewBag.CourseID = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course, and passes all of the required data to the view. The parameters are provided by the **Select** hyperlinks on the page.

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.Courses` navigation property.

```
var viewModel = new InstructorIndexData();
viewModel.Instructors = db.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.Courses.Select(c => c.Department))
     .OrderBy(i => i.LastName);
```

The second `Include` method loads Courses, and for each Course that is loaded it does eager loading for the `Course.Department` navigation property.

```
.Include(i => i.Courses.Select(c => c.Department))
```

As mentioned previously, eager loading is not required but is done to improve performance. Since the view always requires the `OfficeAssignment` entity, it's more efficient to fetch that in the same query. `Course` entities are required when an instructor is selected in the web page, so eager loading is better than lazy loading only if the page is displayed more often with a course selected than without.

If an instructor ID was selected, the selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the `Course` entities from that instructor's `Courses` navigation property.

```
if (id != null)
{
    ViewBag.InstructorID = id.Value;
    viewModel.Courses = viewModel.Instructors.Where(i => i.ID == id.Value).Single().Courses;
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single `Instructor` entity being returned. The `Single` method converts the collection into a single `Instructor` entity, which gives you access to that entity's `Courses` property.

You use the Single method on a collection when you know the collection will have only one item. The `Single` method throws an exception if the collection passed to it is empty or if there's more than one item. An alternative is SingleOrDefault, which returns a default value (`null` in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a `null` reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the `Where` condition instead of calling the `Where` method separately:

```
.Single(i => i.ID == id.Value)
```

Instead of:

```
.Where(I => i.ID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the `Enrollment` entities from that course's `Enrollments` navigation property.

```
if (courseID != null)
{
    ViewBag.CourseID = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Modify the Instructor Index View

In *Views\Instructor\Index.cshtml*, replace the template code with the following code. The changes are highlighted:

```
@model ContosoUniversity.ViewModels.InstructorIndexData

@{
    ViewBag.Title = "Instructors";
}

<h2>Instructors</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table class="table">
    <tr>
        <th>Last Name</th>
        <th>First Name</th>
        <th>Hire Date</th>
        <th>Office</th>
        <th></th>
    </tr>

    @foreach (var item in Model.Instructors)
    {
        string selectedRow = "";
        if (item.ID == ViewBag.InstructorID)
        {
            selectedRow = "success";
        }
        <tr class="@selectedRow">
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.HireDate)
            </td>
            <td>
                @if (item.OfficeAssignment != null)
                {
                    @item.OfficeAssignment.Location
                }
            </td>
            <td>
                @Html.ActionLink("Select", "Index", new { id = item.ID }) |
                @Html.ActionLink("Edit", "Edit", new { id = item.ID }) |
                @Html.ActionLink("Details", "Details", new { id = item.ID }) |
                @Html.ActionLink("Delete", "Delete", new { id = item.ID })
            </td>
        </tr>
    }

    </table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` is not null. (Because this is a one-to-zero-or-one relationship, there might not be a related `OfficeAssignment` entity.)

```
<td>
    @if (item.OfficeAssignment != null)
    {
        @item.OfficeAssignment.Location
    }
</td>
```

- Added code that will dynamically add `class="success"` to the `tr` element of the selected instructor. This sets a background color for the selected row using a Bootstrap class.

```
string selectedRow = "";
if (item.InstructorID == ViewBag.InstructorID)
{
    selectedRow = "success";
}
<tr class="@selectedRow" valign="top">
```

- Added a new `ActionLink` labeled **Select** immediately before the other links in each row, which causes the selected instructor ID to be sent to the `Index` method.

Run the application and select the **Instructors** tab. The page displays the `Location` property of related `OfficeAssignment` entities and an empty table cell when there's no related `OfficeAssignment` entity.

In the *Views\Instructor\Index.cshtml* file, after the closing `table` element (at the end of the file), add the following code. This code displays a list of courses related to an instructor when an instructor is selected.

```
@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == ViewBag.CourseID)
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a `Select` hyperlink that sends the ID of the selected course to the `Index` action method.

Run the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.

After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the `Enrollments` property of the view model in order to display a list of students enrolled in the course.

Run the page and select an instructor. Then select a course to see the list of enrolled students and their grades.

Adding Explicit Loading

Open *InstructorController.cs* and look at how the `Index` method gets the list of enrollments for a selected course:

```
if (courseID != null)
{
    ViewBag.CourseID = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

When you retrieved the list of instructors, you specified eager loading for the `Courses` navigation property and for the `Department` property of each course. Then you put the `Courses` collection in the view model, and now you're accessing the `Enrollments` navigation property from one entity in that collection. Because you didn't specify eager loading for the `Course.Enrollments` navigation property, the data from that property is appearing in the page as a result of lazy loading.

If you disabled lazy loading without changing the code in any other way, the `Enrollments` property would be null regardless of how many enrollments the course actually had. In that case, to load the `Enrollments` property, you'd have to specify either eager loading or explicit loading. You've already seen how to do eager loading. In order to see an example of explicit loading, replace the `Index` method with the following code, which explicitly loads the `Enrollments` property. The code changed are highlighted.

```
public ActionResult Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();

    viewModel.Instructors = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses.Select(c => c.Department))
        .OrderBy(i => i.LastName);

    if (id != null)
    {
        ViewBag.InstructorID = id.Value;
        viewModel.Courses = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single().Courses;
    }

    if (courseID != null)
    {
        ViewBag.CourseID = courseID.Value;
        // Lazy loading
        //viewModel.Enrollments = viewModel.Courses.Where(
        //    x => x.CourseID == courseID).Single().Enrollments;
        // Explicit loading
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID == courseID).Single();
        db.Entry(selectedCourse).Collection(x => x.Enrollments).Load();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            db.Entry(enrollment).Reference(x => x.Student).Load();
        }

        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

After getting the selected `Course` entity, the new code explicitly loads that course's `Enrollments` navigation property:

```
db.Entry(selectedCourse).Collection(x => x.Enrollments).Load();
```

Then it explicitly loads each `Enrollment` entity's related `Student` entity:

```
db.Entry(enrollment).Reference(x => x.Student).Load();
```

Notice that you use the `Collection` method to load a collection property, but for a property that holds just one entity, you use the `Reference` method.

Run the Instructor Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Get the code

Next steps

In this tutorial, you:

- Learned how to load related data
- Created a Courses page
- Created an Instructors page

Advance to the next article to learn how to update related data.

Update related data

Tutorial: Update related data with EF in an ASP.NET MVC app

2/20/2020 • 19 minutes to read • Edit Online

In the previous tutorial you displayed related data. In this tutorial you'll update related data. For most relationships, this can be done by updating either foreign key fields or navigation properties. For many-to-many relationships, the Entity Framework doesn't expose the join table directly, so you add and remove entities to and from the appropriate navigation properties.

The following illustrations show some of the pages that you'll work with.

In this tutorial, you:

- Customize courses pages
- Add office to instructors page
- Add courses to instructors page
- Update DeleteConfirmed
- Add office location and courses to the Create page

Prerequisites

- Reading Related Data

Customize courses pages

When a new course entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate `Department` entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In *CourseController.cs*, delete the four `Create` and `Edit` methods and replace them with the following code:

```
public ActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}

[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create([Bind(Include = "CourseID,Title,Credits,DepartmentID")]Course course)
{
    try
    {
        if (ModelState.IsValid)
        {
            db.Courses.Add(course);
            db.SaveChanges();
            return RedirectToAction("Index");
        }
    }
    catch (RetryLimitExceededException /* dex */)
    {
        //Log the error (uncomment dex variable name and add a line here to write a log.)
        ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see your
system administrator.");
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}

public ActionResult Edit(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Course course = db.Courses.Find(id);
    if (course == null)
    {
        return HttpNotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}

[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public ActionResult EditPost(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    var courseToUpdate = db.Courses.Find(id);
    if (TryUpdateModel(courseToUpdate, "",
       new string[] { "Title", "Credits", "DepartmentID" }))
    {
        try
        {
            db.SaveChanges();

            return RedirectToAction("Index");
        }
        catch (RetryLimitExceededException /* dex */)
        {
            //Log the error (uncomment dex variable name and add a line here to write a log.
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
```

```
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
        }
    }
    PopulateDepartmentsDropDownList(courseToUpdate.DepartmentID);
    return View(courseToUpdate);
}

private void PopulateDepartmentsDropDownList(object selectedDepartment = null)
{
    var departmentsQuery = from d in db.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery, "DepartmentID", "Name", selectedDepartment);
}
```

Add the following `using` statement at the beginning of the file:

```
using System.Data.Entity.Infrastructure;
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in a `ViewBag` property. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name `DepartmentID` to the DropDownList helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named `DepartmentID`.

The `HttpGet` `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item, because for a new course the department is not established yet:

```
public ActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The `HttpGet` `Edit` method sets the selected item, based on the ID of the department that is already assigned to the course being edited:

```
public ActionResult Edit(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Course course = db.Courses.Find(id);
    if (course == null)
    {
        return HttpNotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The `HttpPost` methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error:

```
catch (RetryLimitExceededException /* dex */)
{
    //Log the error (uncomment dex variable name and add a line here to write a log.)
    ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see your
system administrator.");
}
PopulateDepartmentsDropDownList(course.DepartmentID);
return View(course);
```

This code ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

The Course views are already scaffolded with drop-down lists for the department field, but you don't want the DepartmentID caption for this field, so make the following highlighted change to the *Views\Course\Create.cshtml* file to change the caption.

```
@model ContosoUniversity.Models.Course

@{
    ViewBag.Title = "Create";
}

<h2>Create</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()

    <div class="form-horizontal">
        <h4>Course</h4>
        <hr />
        @Html.ValidationSummary(true)

        <div class="form-group">
            @Html.LabelFor(model => model.CourseID, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.CourseID)
                @Html.ValidationMessageFor(model => model.CourseID)
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Title, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Title)
                @Html.ValidationMessageFor(model => model.Title)
            </div>
        </div>

        <div class="form-group">
            @Html.LabelFor(model => model.Credits, new { @class = "control-label col-md-2" })
            <div class="col-md-10">
                @Html.EditorFor(model => model.Credits)
                @Html.ValidationMessageFor(model => model.Credits)
            </div>
        </div>

        <div class="form-group">
            <label class="control-label col-md-2" for="DepartmentID">Department</label>
            <div class="col-md-10">
                @Html.DropDownList("DepartmentID", String.Empty)
                @Html.ValidationMessageFor(model => model.DepartmentID)
            </div>
        </div>

        <div class="form-group">
            <div class="col-md-offset-2 col-md-10">
                <input type="submit" value="Create" class="btn btn-default" />
            </div>
        </div>
    </div>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

Make the same change in *Views\Course\Edit.cshtml*.

Normally the scaffolder doesn't scaffold a primary key because the key value is generated by the database and can't be changed and isn't a meaningful value to be displayed to users. For Course entities the scaffolder does include an text box for the `CourseID` field because it understands that the `DatabaseGeneratedOption.None` attribute means the user should be able enter the primary key value. But it doesn't understand that because the number is meaningful you want to see it in the other views, so you need to add it manually.

In *Views\Course\Edit.cshtml*, add a course number field before the **Title** field. Because it's the primary key, it's displayed, but it can't be changed.

```
<div class="form-group">
    @Html.LabelFor(model => model.CourseID, new { @class = "control-label col-md-2" })
    <div class="col-md-10">
        @Html.DisplayFor(model => model.CourseID)
    </div>
</div>
```

There's already a hidden field (`Html.HiddenFor` helper) for the course number in the Edit view. Adding an *Html.LabelFor* helper doesn't eliminate the need for the hidden field because it doesn't cause the course number to be included in the posted data when the user clicks **Save** on the Edit page.

In *Views\Course\Delete.cshtml* and *Views\Course\Details.cshtml*, change the department name caption from "Name" to "Department" and add a course number field before the **Title** field.

```
<dt>
    Department
</dt>

<dd>
    @Html.DisplayFor(model => model.Department.Name)
</dd>

<dt>
    @Html.DisplayNameFor(model => model.CourseID)
</dt>

<dd>
    @Html.DisplayFor(model => model.CourseID)
</dd>
```

Run the **Create** page (display the Course Index page and click **Create New**) and enter data for a new course:

VALUE	SETTING
Number	Enter *1000*.
Title	Enter *Algebra*.
Credits	Enter *4*.
Department	Select **Mathematics**.

Click **Create**. The Course Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Run the **Edit** page (display the Course Index page and click **Edit** on a course).

Change data on the page and click **Save**. The Course Index page is displayed with the updated course data.

Add office to instructors page

When you edit an instructor record, you want to be able to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity, which means you must handle the following situations:

- If the user clears the office assignment and it originally had a value, you must remove and delete the `OfficeAssignment` entity.
- If the user enters an office assignment value and it originally was empty, you must create a new `OfficeAssignment` entity.
- If the user changes the value of an office assignment, you must change the value in an existing `OfficeAssignment` entity.

Open *InstructorController.cs* and look at the `HttpGet` `Edit` method:

```
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Instructor instructor = db.Instructors.Find(id);
    if (instructor == null)
    {
        return HttpNotFound();
    }
    ViewBag.ID = new SelectList(db.OfficeAssignments, "InstructorID", "Location", instructor.ID);
    return View(instructor);
}
```

The scaffolded code here isn't what you want. It's setting up data for a drop-down list, but you what you need is a text box. Replace this method with the following code:

```
public ActionResult Edit(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Instructor instructor = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Where(i => i.ID == id)
        .Single();
    if (instructor == null)
    {
        return HttpNotFound();
    }
    return View(instructor);
}
```

This code drops the `ViewBag` statement and adds eager loading for the associated `OfficeAssignment` entity. You can't perform eager loading with the `Find` method, so the `Where` and `Single` methods are used instead to select the instructor.

Replace the `HttpPost` `Edit` method with the following code. which handles office assignment updates:

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public ActionResult EditPost(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    var instructorToUpdate = db.Instructors
       .Include(i => i.OfficeAssignment)
       .Where(i => i.ID == id)
       .Single();

    if (TryUpdateModel(instructorToUpdate, "",
       new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
    {
       try
       {
          if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
          {
             instructorToUpdate.OfficeAssignment = null;
          }

          db.SaveChanges();

          return RedirectToAction("Index");
       }
       catch (RetryLimitExceededException /* dex */)
      {
         //Log the error (uncomment dex variable name and add a line here to write a log.
         ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
      }
   }
   return View(instructorToUpdate);
}
```

The reference to `RetryLimitExceededException` requires a `using` statement; to add it - hover your mouse over `RetryLimitExceededException`. The following message appears:

Select **Show potential fixes**, then **using System.Data.Entity.Infrastructure**

The code does the following:

- Changes the method name to `EditPost` because the signature is now the same as the `HttpGet` method (the `ActionName` attribute specifies that the /Edit/ URL is still used).
- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property. This is the same as what you did in the `HttpGet` `Edit` method.

- Updates the retrieved `Instructor` entity with values from the model binder. The TryUpdateModel overload used enables you to *whitelist* the properties you want to include. This prevents over-posting, as explained in the second tutorial.

```
if (TryUpdateModel(instructorToUpdate, "",
      new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
```

- If the office location is blank, sets the `Instructor.OfficeAssignment` property to null so that the related row in the `OfficeAssignment` table will be deleted.

```
if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
{
    instructorToUpdate.OfficeAssignment = null;
}
```

- Saves the changes to the database.

In *Views\Instructor\Edit.cshtml*, after the `div` elements for the **Hire Date** field, add a new field for editing the office location:

```
<div class="form-group">
    @Html.LabelFor(model => model.OfficeAssignment.Location, new { @class = "control-label col-md-2" })
    <div class="col-md-10">
        @Html.EditorFor(model => model.OfficeAssignment.Location)
        @Html.ValidationMessageFor(model => model.OfficeAssignment.Location)
    </div>
</div>
```

Run the page (select the **Instructors** tab and then click **Edit** on an instructor). Change the **Office Location** and click **Save**.

Add courses to instructors page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of check boxes.

The relationship between the `Course` and `Instructor` entities is many-to-many, which means you do not have direct access to the foreign key properties which are in the join table. Instead, you add and remove entities to and from the `Instructor.Courses` navigation property.

The UI that enables you to change which courses an instructor is assigned to is a group of check boxes. A check box for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear check boxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating navigation properties in order to create or delete relationships.

To provide data to the view for the list of check boxes, you'll use a view model class. Create *AssignedCourseData.cs* in the *ViewModels* folder and replace the existing code with the following code:

```
namespace ContosoUniversity.ViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In *InstructorController.cs*, replace the `HttpGet` `Edit` method with the following code. The changes are highlighted.

```
public ActionResult Edit(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Instructor instructor = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses)
        .Where(i => i.ID == id)
        .Single();
    PopulateAssignedCourseData(instructor);
    if (instructor == null)
    {
        return HttpNotFound();
    }
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
    var allCourses = db.Courses;
    var instructorCourses = new HashSet<int>(instructor.Courses.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewBag.Courses = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the check box array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all `Course` entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a HashSet collection. The `Assigned` property is set to `true` for courses the instructor is assigned. The view will use this property to determine which check boxes must be displayed as selected. Finally, the list is passed to the view in a `ViewBag` property.

Next, add the code that's executed when the user clicks **Save**. Replace the `EditPost` method with the following code, which calls a new method that updates the `Courses` navigation property of the `Instructor` entity. The

changes are highlighted.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(int? id, string[] selectedCourses)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    var instructorToUpdate = db.Instructors
       .Include(i => i.OfficeAssignment)
       .Include(i => i.Courses)
       .Where(i => i.ID == id)
       .Single();

    if (TryUpdateModel(instructorToUpdate, "",
       new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
    {
        try
        {
            if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }

            UpdateInstructorCourses(selectedCourses, instructorToUpdate);

            db.SaveChanges();

            return RedirectToAction("Index");
        }
        catch (RetryLimitExceededException /* dex */)
        {
            //Log the error (uncomment dex variable name and add a line here to write a log.
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
        }
    }
    PopulateAssignedCourseData(instructorToUpdate);
    return View(instructorToUpdate);
}
private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
   if (selectedCourses == null)
   {
      instructorToUpdate.Courses = new List<Course>();
      return;
   }

   var selectedCoursesHS = new HashSet<string>(selectedCourses);
   var instructorCourses = new HashSet<int>
       (instructorToUpdate.Courses.Select(c => c.CourseID));
   foreach (var course in db.Courses)
   {
      if (selectedCoursesHS.Contains(course.CourseID.ToString()))
      {
         if (!instructorCourses.Contains(course.CourseID))
         {
            instructorToUpdate.Courses.Add(course);
         }
      }
      else
      {
         if (instructorCourses.Contains(course.CourseID))
         {
            instructorToUpdate.Courses.Remove(course);
         }
```

```
        }
    }
}
```

The method signature is now different from the `HttpGet` `Edit` method, so the method name changes from `EditPost` back to `Edit`.

Since the view doesn't have a collection of `Course` entities, the model binder can't automatically update the `Courses` navigation property. Instead of using the model binder to update the `Courses` navigation property, you'll do that in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `Courses` property from model binding. This doesn't require any change to the code that calls TryUpdateModel because you're using the *whitelisting* overload and `Courses` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `Courses` navigation property with an empty collection:

```
if (selectedCourses == null)
{
    instructorToUpdate.Courses = new List<Course>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.Courses` navigation property, the course is added to the collection in the navigation property.

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Add(course);
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.Courses` navigation property, the course is removed from the navigation property.

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Remove(course);
    }
}
```

In *Views\Instructor\Edit.cshtml*, add a **Courses** field with an array of check boxes by adding the following code immediately after the `div` elements for the `OfficeAssignment` field and before the `div` element for the **Save** button:

```
<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.ViewModels.AssignedCourseData> courses = ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                               name="selectedCourses"
                               value="@course.CourseID"
                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                               @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

After you paste the code, if line breaks and indentation don't look like they do here, manually fix everything so that it looks like what you see here. The indentation doesn't have to be perfect, but the `@</tr><tr>`, `@:<td>`, `@:</td>`, and `@</tr>` lines must each be on a single line as shown or you'll get a runtime error.

This code creates an HTML table that has three columns. In each column is a check box followed by a caption that consists of the course number and title. The check boxes all have the same name ("selectedCourses"), which informs the model binder that they are to be treated as a group. The `value` attribute of each check box is set to the value of `CourseID.` When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the check boxes which are selected.

When the check boxes are initially rendered, those that are for courses assigned to the instructor have `checked` attributes, which selects them (displays them checked).

After changing course assignments, you'll want to be able to verify the changes when the site returns to the `Index` page. Therefore, you need to add a column to the table in that page. In this case you don't need to use the `ViewBag` object, because the information you want to display is already in the `Courses` navigation property of the `Instructor` entity that you're passing to the page as the model.

In *Views\Instructor\Index.cshtml*, add a **Courses** heading immediately following the **Office** heading, as shown in the following example:

```
<tr>
    <th>Last Name</th>
    <th>First Name</th>
    <th>Hire Date</th>
    <th>Office</th>
    <th>Courses</th>
    <th></th>
</tr>
```

Then add a new detail cell immediately following the office location detail cell:

```
<td>
    @if (item.OfficeAssignment != null)
    {
        @item.OfficeAssignment.Location
    }
</td>
<td>
    @{
        foreach (var course in item.Courses)
        {
            @course.CourseID @:  @course.Title <br />
        }
    }
</td>
<td>
    @Html.ActionLink("Select", "Index", new { id = item.ID }) |
    @Html.ActionLink("Edit", "Edit", new { id = item.ID }) |
    @Html.ActionLink("Details", "Details", new { id = item.ID }) |
    @Html.ActionLink("Delete", "Delete", new { id = item.ID })
</td>
```

Run the **Instructor Index** page to see the courses assigned to each instructor.

Click **Edit** on an instructor to see the Edit page.

Change some course assignments and click **Save**. The changes you make are reflected on the Index page.

Note: The approach taken here to edit instructor course data works well when there is a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update DeleteConfirmed

In *InstructorController.cs*, delete the `DeleteConfirmed` method and insert the following code in its place.

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public ActionResult DeleteConfirmed(int id)
{
   Instructor instructor = db.Instructors
     .Include(i => i.OfficeAssignment)
     .Where(i => i.ID == id)
     .Single();

   db.Instructors.Remove(instructor);

    var department = db.Departments
        .Where(d => d.InstructorID == id)
        .SingleOrDefault();
    if (department != null)
    {
        department.InstructorID = null;
    }

   db.SaveChanges();
   return RedirectToAction("Index");
}
```

This code makes the following change:

- If the instructor is assigned as administrator of any department, removes the instructor assignment from that department. Without this code, you would get a referential integrity error if you tried to delete an instructor who was assigned as administrator for a department.

This code doesn't handle the scenario of one instructor assigned as administrator for multiple departments. In the last tutorial you'll add code that prevents that scenario from happening.

Add office location and courses to the Create page

In *InstructorController.cs*, delete the `HttpGet` and `HttpPost` `Create` methods, and then add the following code in their place:

```
public ActionResult Create()
{
    var instructor = new Instructor();
    instructor.Courses = new List<Course>();
    PopulateAssignedCourseData(instructor);
    return View();
}

[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create([Bind(Include = "LastName,FirstMidName,HireDate,OfficeAssignment" )]Instructor
instructor, string[] selectedCourses)
{
    if (selectedCourses != null)
    {
        instructor.Courses = new List<Course>();
        foreach (var course in selectedCourses)
        {
            var courseToAdd = db.Courses.Find(int.Parse(course));
            instructor.Courses.Add(courseToAdd);
        }
    }
    if (ModelState.IsValid)
    {
        db.Instructors.Add(instructor);
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}
```

This code is similar to what you saw for the Edit methods except that initially no courses are selected. The `HttpGet` `Create` method calls the `PopulateAssignedCourseData` method not because there might be courses selected but in order to provide an empty collection for the `foreach` loop in the view (otherwise the view code would throw a null reference exception).

The HttpPost Create method adds each selected course to the Courses navigation property before the template code that checks for validation errors and adds the new instructor to the database. Courses are added even if there are model errors so that when there are model errors (for an example, the user keyed an invalid date) so that when the page is redisplayed with an error message, any course selections that were made are automatically restored.

Notice that in order to be able to add courses to the `Courses` navigation property you have to initialize the property as an empty collection:

```
instructor.Courses = new List<Course>();
```

As an alternative to doing this in controller code, you could do it in the Instructor model by changing the property getter to automatically create the collection if it doesn't exist, as shown in the following example:

```
private ICollection<Course> _courses;
public virtual ICollection<Course> Courses
{
    get
    {
        return _courses ?? (_courses = new List<Course>());
    }
    set
    {
        _courses = value;
    }
}
```

If you modify the `Courses` property in this way, you can remove the explicit property initialization code in the controller.

In *Views\Instructor\Create.cshtml*, add an office location text box and course check boxes after the hire date field and before the **Submit** button.

```
<div class="form-group">
    @Html.LabelFor(model => model.OfficeAssignment.Location, new { @class = "control-label col-md-2" })
    <div class="col-md-10">
        @Html.EditorFor(model => model.OfficeAssignment.Location)
        @Html.ValidationMessageFor(model => model.OfficeAssignment.Location)
    </div>
</div>

<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;
                    List<ContosoUniversity.ViewModels.AssignedCourseData> courses = ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                               name="selectedCourses"
                               value="@course.CourseID"
                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                               @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

After you paste the code, fix line breaks and indentation as you did earlier for the Edit page.

Run the Create page and add an instructor.

Handling transactions

As explained in the Basic CRUD Functionality tutorial, by default the Entity Framework implicitly implements transactions. For scenarios where you need more control -- for example, if you want to include operations done

outside of Entity Framework in a transaction -- see Working with Transactions on MSDN.

Get the code

Download the Completed Project

Additional resources

Links to other Entity Framework resources can be found in ASP.NET Data Access - Recommended Resources.

Next step

In this tutorial, you:

- Customized courses pages
- Added office to instructors page
- Added courses to instructors page
- Updated DeleteConfirmed
- Added office location and courses to the Create page

Advance to the next article to learn how to implement an asynchronous programming model.

Asynchronous programming model

Tutorial: Use async and stored procedures with EF in an ASP.NET MVC App

2/20/2020 • 8 minutes to read • Edit Online

In earlier tutorials you learned how to read and update data using the synchronous programming model. In this tutorial you see how to implement the asynchronous programming model. Asynchronous code can help an application perform better because it makes better use of server resources.

In this tutorial you also see how to use stored procedures for insert, update, and delete operations on an entity.

Finally, you redeploy the application to Azure, along with all of the database changes that you've implemented since the first time you deployed.

The following illustrations show some of the pages that you'll work with.

In this tutorial, you:

- Learn about asynchronous code
- Create a Department controller
- Use stored procedures
- Deploy to Azure

Prerequisites

- Updating Related Data

Why use asynchronous code

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be use more efficiently, and the server is enabled to handle more traffic without delays.

In earlier versions of .NET, writing and testing asynchronous code was complex, error prone, and hard to debug. In .NET 4.5, writing, testing, and debugging asynchronous code is so much easier that you should generally write asynchronous code unless you have a reason not to. Asynchronous code does introduce a small amount of overhead, but for low traffic situations the performance hit is negligible, while for high traffic situations, the

potential performance improvement is substantial.

For more information about asynchronous programming, see Use .NET 4.5's async support to avoid blocking calls.

Create Department controller

Create a Department controller the same way you did the earlier controllers, except this time select the **Use async controller actions** check box.

The following highlights show what was added to the synchronous code for the `Index` method to make it asynchronous:

```
public async Task<ActionResult> Index()
{
    var departments = db.Departments.Include(d => d.Administrator);
    return View(await departments.ToListAsync());
}
```

Four changes were applied to enable the Entity Framework database query to execute asynchronously:

- The method is marked with the `async` keyword, which tells the compiler to generate callbacks for parts of the method body and to automatically create the `Task<ActionResult>` object that is returned.
- The return type was changed from `ActionResult` to `Task<ActionResult>`. The `Task<T>` type represents ongoing work with a result of type `T`.
- The `await` keyword was applied to the web service call. When the compiler sees this keyword, behind the scenes it splits the method into two parts. The first part ends with the operation that is started asynchronously. The second part is put into a callback method that is called when the operation completes.
- The asynchronous version of the `ToList` extension method was called.

Why is the `departments.ToList` statement modified but not the `departments = db.Departments` statement? The reason is that only statements that cause queries or commands to be sent to the database are executed asynchronously. The `departments = db.Departments` statement sets up a query but the query is not executed until the `ToList` method is called. Therefore, only the `ToList` method is executed asynchronously.

In the `Details` method and the `HttpGet` `Edit` and `Delete` methods, the `Find` method is the one that causes a query to be sent to the database, so that's the method that gets executed asynchronously:

```
public async Task<ActionResult> Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Department department = await db.Departments.FindAsync(id);
    if (department == null)
    {
        return HttpNotFound();
    }
    return View(department);
}
```

In the `Create`, `HttpPost Edit`, and `DeleteConfirmed` methods, it is the `SaveChanges` method call that causes a command to be executed, not statements such as `db.Departments.Add(department)` which only cause entities in memory to be modified.

```
public async Task<ActionResult> Create(Department department)
{
    if (ModelState.IsValid)
    {
        db.Departments.Add(department);
    await db.SaveChangesAsync();
        return RedirectToAction("Index");
    }
```

Open *Views\Department\Index.cshtml*, and replace the template code with the following code:

```
@model IEnumerable<ContosoUniversity.Models.Department>
@{
    ViewBag.Title = "Departments";
}
<h2>Departments</h2>
<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table class="table">
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Name)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Budget)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.StartDate)
        </th>
    <th>
            Administrator
        </th>
        <th></th>
    </tr>
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Budget)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.StartDate)
        </td>
    <td>
            @Html.DisplayFor(modelItem => item.Administrator.FullName)
            </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.DepartmentID }) |
            @Html.ActionLink("Details", "Details", new { id=item.DepartmentID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.DepartmentID })
        </td>
    </tr>
}
</table>
```

This code changes the title from Index to Departments, moves the Administrator name to the right, and provides the full name of the administrator.

In the Create, Delete, Details, and Edit views, change the caption for the `InstructorID` field to "Administrator" the same way you changed the department name field to "Department" in the Course views.

In the Create and Edit views use the following code:

```
<label class="control-label col-md-2" for="InstructorID">Administrator</label>
```

In the Delete and Details views use the following code:

```
<dt>
    Administrator
</dt>
```

Run the application, and click the **Departments** tab.

Everything works the same as in the other controllers, but in this controller all of the SQL queries are executing asynchronously.

Some things to be aware of when you are using asynchronous programming with the Entity Framework:

- The async code is not thread safe. In other words, in other words, don't try to do multiple operations in parallel using the same context instance.
- If you want to take advantage of the performance benefits of async code, make sure that any library packages that you're using (such as for paging), also use async if they call any Entity Framework methods that cause queries to be sent to the database.

Use stored procedures

Some developers and DBAs prefer to use stored procedures for database access. In earlier versions of Entity Framework you can retrieve data using a stored procedure by executing a raw SQL query, but you can't instruct EF to use stored procedures for update operations. In EF 6 it's easy to configure Code First to use stored procedures.

1. In *DAL\SchoolContext.cs*, add the highlighted code to the `OnModelCreating` method.

   ```
   protected override void OnModelCreating(DbModelBuilder modelBuilder)
   {
       modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();
       modelBuilder.Entity<Course>()
           .HasMany(c => c.Instructors).WithMany(i => i.Courses)
           .Map(t => t.MapLeftKey("CourseID")
               .MapRightKey("InstructorID")
               .ToTable("CourseInstructor"));
       modelBuilder.Entity<Department>().MapToStoredProcedures();
   }
   ```

   This code instructs Entity Framework to use stored procedures for insert, update, and delete operations on the `Department` entity.

2. In Package Manage Console, enter the following command:

   ```
   add-migration DepartmentSP
   ```

   Open *Migrations\<timestamp>_DepartmentSP.cs* to see the code in the `Up` method that creates Insert, Update, and Delete stored procedures:

```
public override void Up()
{
    CreateStoredProcedure(
        "dbo.Department_Insert",
        p => new
            {
                Name = p.String(maxLength: 50),
                Budget = p.Decimal(precision: 19, scale: 4, storeType: "money"),
                StartDate = p.DateTime(),
                InstructorID = p.Int(),
            },
        body:
            @"INSERT [dbo].[Department]([Name], [Budget], [StartDate], [InstructorID])
              VALUES (@Name, @Budget, @StartDate, @InstructorID)

              DECLARE @DepartmentID int
              SELECT @DepartmentID = [DepartmentID]
              FROM [dbo].[Department]
              WHERE @@ROWCOUNT > 0 AND [DepartmentID] = scope_identity()

              SELECT t0.[DepartmentID]
              FROM [dbo].[Department] AS t0
              WHERE @@ROWCOUNT > 0 AND t0.[DepartmentID] = @DepartmentID"
    );

    CreateStoredProcedure(
        "dbo.Department_Update",
        p => new
            {
                DepartmentID = p.Int(),
                Name = p.String(maxLength: 50),
                Budget = p.Decimal(precision: 19, scale: 4, storeType: "money"),
                StartDate = p.DateTime(),
                InstructorID = p.Int(),
            },
        body:
            @"UPDATE [dbo].[Department]
              SET [Name] = @Name, [Budget] = @Budget, [StartDate] = @StartDate, [InstructorID] =
@InstructorID
              WHERE ([DepartmentID] = @DepartmentID)"
    );

    CreateStoredProcedure(
        "dbo.Department_Delete",
        p => new
            {
                DepartmentID = p.Int(),
            },
        body:
            @"DELETE [dbo].[Department]
              WHERE ([DepartmentID] = @DepartmentID)"
    );
}
```

3. In Package Manage Console, enter the following command:

   `update-database`

4. Run the application in debug mode, click the **Departments** tab, and then click **Create New**.

5. Enter data for a new department, and then click **Create**.

6. In Visual Studio, look at the logs in the **Output** window to see that a stored procedure was used to insert the new Department row.

```
Output
Show output from: Debug

```

Code First creates default stored procedure names. If you are using an existing database, you might need to customize the stored procedure names in order to use stored procedures already defined in the database. For information about how to do that, see Entity Framework Code First Insert/Update/Delete Stored Procedures.

If you want to customize what generated stored procedures do, you can edit the scaffolded code for the migrations `Up` method that creates the stored procedure. That way your changes are reflected whenever that migration is run and will be applied to your production database when migrations runs automatically in production after deployment.

If you want to change an existing stored procedure that was created in a previous migration, you can use the Add-Migration command to generate a blank migration, and then manually write code that calls the AlterStoredProcedure method.

Deploy to Azure

This section requires you to have completed the optional **Deploying the app to Azure** section in the Migrations and Deployment tutorial of this series. If you had migrations errors that you resolved by deleting the database in your local project, skip this section.

1. In Visual Studio, right-click the project in **Solution Explorer** and select **Publish** from the context menu.
2. Click **Publish**.

   Visual Studio deploys the application to Azure, and the application opens in your default browser, running in Azure.
3. Test the application to verify it's working.

   The first time you run a page that accesses the database, the Entity Framework runs all of the migrations `Up` methods required to bring the database up to date with the current data model. You can now use all of the web pages that you added since the last time you deployed, including the Department pages that you added in this tutorial.

Get the code

Next steps

In this tutorial, you:

- Learned about asynchronous code
- Created a Department controller
- Used stored procedures
- Deployed to Azure

Advance to the next article to learn how to handle conflicts when multiple users update the same entity at the same time.

Handling concurrency

Tutorial: Handle Concurrency with EF in an ASP.NET MVC 5 app

2/20/2020 • 16 minutes to read • Edit Online

In earlier tutorials you learned how to update data. This tutorial shows how to use optimistic concurrency to handle conflicts when multiple users update the same entity at the same time. You change the web pages that work with the `Department` entity so that they handle concurrency errors. The following illustrations show the Edit and Delete pages, including some messages that are displayed if a concurrency conflict occurs.

In this tutorial, you:

- Learn about concurrency conflicts
- Add optimistic concurrency
- Modify Department controller
- Test concurrency handling
- Update the Delete page

Prerequisites

- Async and Stored Procedures

Concurrency conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.

Pessimistic Concurrency (Locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called *pessimistic concurrency*. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.

Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases. For these reasons, not all database management systems support pessimistic concurrency. The Entity Framework provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency

The alternative to pessimistic concurrency is *optimistic concurrency*. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, John runs the Departments Edit page, changes the **Budget** amount for the English department from $350,000.00 to $0.00.

Before John clicks **Save**, Jane runs the same page and changes the **Start Date** field from 9/1/2007 to 8/8/2013.

John clicks **Save** first and sees his change when the browser returns to the Index page, then Jane clicks **Save**. What happens next is determined by how you handle concurrency conflicts. Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database. In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they'll see both John's and Jane's changes — a start date of 8/8/2013 and a budget of Zero dollars.

  This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are made to the same property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields) or in a cookie.

- You can let Jane's change overwrite John's change. The next time someone browses the English department, they'll see 8/8/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent Jane's change from being updated in the database. Typically, you would display an error message, show her the current state of the data, and allow her to reapply her changes if she still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted to what's happening.

Detecting Concurrency Conflicts

You can resolve conflicts by handling OptimisticConcurrencyException exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the `Where` clause of SQL

`Update` or `Delete` commands.

The data type of the tracking column is typically rowversion. The rowversion value is a sequential number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the original value of the tracking column (the original row version). If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the `Update` or `Delete` statement can't find the row to update because of the `Where` clause. When the Entity Framework finds that no rows have been updated by the `Update` or `Delete` command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the `Where` clause of `Update` and `Delete` commands.

  As in the first option, if anything in the row has changed since the row was first read, the `Where` clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large `Where` clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the ConcurrencyCheck attribute to them. That change enables the Entity Framework to include all columns in the SQL `WHERE` clause of `UPDATE` statements.

In the remainder of this tutorial you'll add a rowversion tracking property to the `Department` entity, create a controller and views, and test to verify that everything works correctly.

Add optimistic concurrency

In *Models\Department.cs*, add a tracking property named `RowVersion`:

```
public class Department
{
    public int DepartmentID { get; set; }

    [StringLength(50, MinimumLength = 3)]
    public string Name { get; set; }

    [DataType(DataType.Currency)]
    [Column(TypeName = "money")]
    public decimal Budget { get; set; }

    [DataType(DataType.Date)]
    [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
    [Display(Name = "Start Date")]
    public DateTime StartDate { get; set; }

    [Display(Name = "Administrator")]
    public int? InstructorID { get; set; }

    [Timestamp]
    public byte[] RowVersion { get; set; }

    public virtual Instructor Administrator { get; set; }
    public virtual ICollection<Course> Courses { get; set; }
}
```

The Timestamp attribute specifies that this column will be included in the `Where` clause of `Update` and `Delete`

commands sent to the database. The attribute is called Timestamp because previous versions of SQL Server used a SQL timestamp data type before the SQL rowversion replaced it. The .Net type for rowversion is a byte array.

If you prefer to use the fluent API, you can use the IsConcurrencyToken method to specify the tracking property, as shown in the following example:

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsConcurrencyToken();
```

By adding a property you changed the database model, so you need to do another migration. In the Package Manager Console (PMC), enter the following commands:

```
Add-Migration RowVersion
Update-Database
```

Modify Department controller

In *Controllers\DepartmentController.cs*, add a `using` statement:

```
using System.Data.Entity.Infrastructure;
```

In the *DepartmentController.cs* file, change all four occurrences of "LastName" to "FullName" so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

```
ViewBag.InstructorID = new SelectList(db.Instructors, "ID", "FullName");
```

Replace the existing code for the `HttpPost` `Edit` method with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Edit(int? id, byte[] rowVersion)
{
    string[] fieldsToBind = new string[] { "Name", "Budget", "StartDate", "InstructorID", "RowVersion" };

    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }

    var departmentToUpdate = await db.Departments.FindAsync(id);
    if (departmentToUpdate == null)
    {
        Department deletedDepartment = new Department();
        TryUpdateModel(deletedDepartment, fieldsToBind);
        ModelState.AddModelError(string.Empty,
            "Unable to save changes. The department was deleted by another user.");
        ViewBag.InstructorID = new SelectList(db.Instructors, "ID", "FullName",
deletedDepartment.InstructorID);
        return View(deletedDepartment);
    }

    if (TryUpdateModel(departmentToUpdate, fieldsToBind))
    {
        try
        {
            db.Entry(departmentToUpdate).OriginalValues["RowVersion"] = rowVersion;
            await db.SaveChangesAsync();
```

```
            return RedirectToAction("Index");
        }
        catch (DbUpdateConcurrencyException ex)
        {
            var entry = ex.Entries.Single();
            var clientValues = (Department)entry.Entity;
            var databaseEntry = entry.GetDatabaseValues();
            if (databaseEntry == null)
            {
                ModelState.AddModelError(string.Empty,
                    "Unable to save changes. The department was deleted by another user.");
            }
            else
            {
                var databaseValues = (Department)databaseEntry.ToObject();

                if (databaseValues.Name != clientValues.Name)
                    ModelState.AddModelError("Name", "Current value: "
                        + databaseValues.Name);
                if (databaseValues.Budget != clientValues.Budget)
                    ModelState.AddModelError("Budget", "Current value: "
                        + String.Format("{0:c}", databaseValues.Budget));
                if (databaseValues.StartDate != clientValues.StartDate)
                    ModelState.AddModelError("StartDate", "Current value: "
                        + String.Format("{0:d}", databaseValues.StartDate));
                if (databaseValues.InstructorID != clientValues.InstructorID)
                    ModelState.AddModelError("InstructorID", "Current value: "
                        + db.Instructors.Find(databaseValues.InstructorID).FullName);
                ModelState.AddModelError(string.Empty, "The record you attempted to edit "
                    + "was modified by another user after you got the original value. The "
                    + "edit operation was canceled and the current values in the database "
                    + "have been displayed. If you still want to edit this record, click "
                    + "the Save button again. Otherwise click the Back to List hyperlink.");
                departmentToUpdate.RowVersion = databaseValues.RowVersion;
            }
        }
        catch (RetryLimitExceededException /* dex */)
        {
            //Log the error (uncomment dex variable name and add a line here to write a log.)
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
        }
    }
    ViewBag.InstructorID = new SelectList(db.Instructors, "ID", "FullName", departmentToUpdate.InstructorID);
    return View(departmentToUpdate);
}
```

If the `FindAsync` method returns null, the department was deleted by another user. The code shown uses the posted form values to create a department entity so that the Edit page can be redisplayed with an error message. As an alternative, you wouldn't have to re-create the department entity if you display only an error message without redisplaying the department fields.

The view stores the original `RowVersion` value in a hidden field, and the method receives it in the `rowVersion` parameter. Before you call `SaveChanges`, you have to put that original `RowVersion` property value in the `OriginalValues` collection for the entity. Then when the Entity Framework creates a SQL `UPDATE` command, that command will include a `WHERE` clause that looks for a row that has the original `RowVersion` value.

If no rows are affected by the `UPDATE` command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception, and the code in the `catch` block gets the affected `Department` entity from the exception object.

```
var entry = ex.Entries.Single();
```

This object has the new values entered by the user in its `Entity` property, and you can get the values read from the database by calling the `GetDatabaseValues` method.

```
var clientValues = (Department)entry.Entity;
var databaseEntry = entry.GetDatabaseValues();
```

The `GetDatabaseValues` method returns null if someone has deleted the row from the database; otherwise, you have to cast the returned object to the `Department` class in order to access the `Department` properties. (Because you already checked for deletion, `databaseEntry` would be null only if the department was deleted after `FindAsync` executes and before `SaveChanges` executes.)

```
if (databaseEntry == null)
{
    ModelState.AddModelError(string.Empty,
        "Unable to save changes. The department was deleted by another user.");
}
else
{
    var databaseValues = (Department)databaseEntry.ToObject();
```

Next, the code adds a custom error message for each column that has database values different from what the user entered on the Edit page:

```
if (databaseValues.Name != currentValues.Name)
    ModelState.AddModelError("Name", "Current value: " + databaseValues.Name);
    // ...
```

A longer error message explains what happened and what to do about it:

```
ModelState.AddModelError(string.Empty, "The record you attempted to edit "
    + "was modified by another user after you got the original value. The"
    + "edit operation was canceled and the current values in the database "
    + "have been displayed. If you still want to edit this record, click "
    + "the Save button again. Otherwise click the Back to List hyperlink.");
```

Finally, the code sets the `RowVersion` value of the `Department` object to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

In *Views\Department\Edit.cshtml*, add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property:

```
@model ContosoUniversity.Models.Department

@{
    ViewBag.Title = "Edit";
}

<h2>Edit</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()

    <div class="form-horizontal">
        <h4>Department</h4>
        <hr />
        @Html.ValidationSummary(true)
        @Html.HiddenFor(model => model.DepartmentID)
        @Html.HiddenFor(model => model.RowVersion)
```

Test concurrency handling

Run the site and click **Departments**.

Right click the **Edit** hyperlink for the English department and select **Open in new tab,** then click the **Edit** hyperlink for the English department. The two tabs display the same information.

Change a field in the first browser tab and click **Save**.

The browser shows the Index page with the changed value.

Change a field in the second browser tab and click **Save**. You see an error message:

Click **Save** again. The value you entered in the second browser tab is saved along with the original value of the data you changed in the first browser. You see the saved values when the Index page appears.

Update the Delete page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the `HttpGet` `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the `HttpPost` `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL `DELETE` command, it includes a `WHERE` clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the `HttpGet Delete` method is called with an error flag set to `true` in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case a different error message is displayed.

In *DepartmentController.cs*, replace the `HttpGet` `Delete` method with the following code:

```
public async Task<ActionResult> Delete(int? id, bool? concurrencyError)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Department department = await db.Departments.FindAsync(id);
    if (department == null)
    {
        if (concurrencyError.GetValueOrDefault())
        {
            return RedirectToAction("Index");
        }
        return HttpNotFound();
    }

    if (concurrencyError.GetValueOrDefault())
    {
        ViewBag.ConcurrencyErrorMessage = "The record you attempted to delete "
            + "was modified by another user after you got the original values. "
            + "The delete operation was canceled and the current values in the "
            + "database have been displayed. If you still want to delete this "
            + "record, click the Delete button again. Otherwise "
            + "click the Back to List hyperlink.";
    }

    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is `true`, an error message is sent to the view using a `ViewBag` property.

Replace the code in the `HttpPost` `Delete` method (named `DeleteConfirmed`) with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Delete(Department department)
{
    try
    {
        db.Entry(department).State = EntityState.Deleted;
        await db.SaveChangesAsync();
        return RedirectToAction("Index");
    }
    catch (DbUpdateConcurrencyException)
    {
        return RedirectToAction("Delete", new { concurrencyError = true, id=department.DepartmentID });
    }
    catch (DataException /* dex */)
    {
        //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
        ModelState.AddModelError(string.Empty, "Unable to delete. Try again, and if the problem persists
contact your system administrator.");
        return View(department);
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

```
public async Task<ActionResult> DeleteConfirmed(int id)
```

You've changed this parameter to a `Department` entity instance created by the model binder. This gives you access to the `RowVersion` property value in addition to the record key.

```
public async Task<ActionResult> Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code named the `HttpPost` `Delete` method `DeleteConfirmed` to give the `HttpPost` method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the `HttpPost` and `HttpGet` delete methods.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

In *Views\Department\Delete.cshtml*, replace the scaffolded code with the following code that adds an error message field and hidden fields for the DepartmentID and RowVersion properties. The changes are highlighted.

```
@model ContosoUniversity.Models.Department

@{
    ViewBag.Title = "Delete";
}

<h2>Delete</h2>

<p class="error">@ViewBag.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="dl-horizontal">
        <dt>
            Administrator
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Name)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Name)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.Budget)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.Budget)
        </dd>

        <dt>
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>

        <dd>
            @Html.DisplayFor(model => model.StartDate)
        </dd>

    </dl>

    @using (Html.BeginForm()) {
        @Html.AntiForgeryToken()
        @Html.HiddenFor(model => model.DepartmentID)
        @Html.HiddenFor(model => model.RowVersion)

        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            @Html.ActionLink("Back to List", "Index")
        </div>
    }
</div>
```

This code adds an error message between the `h2` and `h3` headings:

```
<p class="error">@ViewBag.ConcurrencyErrorMessage</p>
```

It replaces `LastName` with `FullName` in the `Administrator` field:

```
<dt>
  Administrator
</dt>
<dd>
  @Html.DisplayFor(model => model.Administrator.FullName)
</dd>
```

Finally, it adds hidden fields for the `DepartmentID` and `RowVersion` properties after the `Html.BeginForm` statement:

```
@Html.HiddenFor(model => model.DepartmentID)
@Html.HiddenFor(model => model.RowVersion)
```

Run the Departments Index page. Right click the **Delete** hyperlink for the English department and select **Open in new tab,** then in the first tab click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save**.

The Index page confirms the change.

In the second tab, click **Delete**.

You see the concurrency error message, and the Department values are refreshed with what's currently in the database.

If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Get the code

For information about other ways to handle various concurrency scenarios, see Optimistic Concurrency Patterns and Working with Property Values on MSDN. The next tutorial shows how to implement table-per-hierarchy inheritance for the `Instructor` and `Student` entities.

Next steps

In this tutorial, you:

- Learned about concurrency conflicts
- Added optimistic concurrency
- Modified Department controller
- Tested concurrency handling

- Updated the Delete page

Advance to the next article to learn how to implement inheritance in the data model.

Implement inheritance in the data model

Tutorial: Implement Inheritance with EF in an ASP.NET MVC 5 app

2/20/2020 • 9 minutes to read • Edit Online

In the previous tutorial you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

In object-oriented programming, you can use inheritance to facilitate code reuse. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

In this tutorial, you:

- Learn to map inheritance to database
- Create the Person class
- Update Instructor and Student
- Add Person to the Model
- Create and Update Migrations
- Test the implementation
- Deploy to Azure

Prerequisites

- Handling Concurrency

Map inheritance to database

The `Instructor` and `Student` classes in the `School` data model have several properties that are identical:

Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. Or you want to write a service that can format names without caring whether the name came from an instructor or a student. You could create a `Person` base class which contains only those shared properties, then make the `Instructor` and `Student` entities inherit from that base class, as shown in the following illustration:

There are several ways this inheritance structure could be represented in the database. You could have a `Person` table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (`HireDate`), some only to students (`EnrollmentDate`), some to both (`LastName`, `FirstName`). Typically, you'd have a *discriminator* column to indicate which type each row represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.

This pattern of generating an entity inheritance structure from a single database table is called *table-per-hierarchy* (TPH) inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the `Person` table and have separate `Instructor` and `Student` tables with the date fields.

This pattern of making a database table for each entity class is called *table per type* (TPT) inheritance.

Yet another option is to map all non-abstract types to individual tables. All properties of a class, including inherited

properties, map to columns of the corresponding table. This pattern is called Table-per-Concrete Class (TPC) inheritance. If you implemented TPC inheritance for the `Person`, `Student`, and `Instructor` classes as shown earlier, the `Student` and `Instructor` tables would look no different after implementing inheritance than they did before.

TPC and TPH inheritance patterns generally deliver better performance in the Entity Framework than TPT inheritance patterns, because TPT patterns can result in complex join queries.

This tutorial demonstrates how to implement TPH inheritance. TPH is the default inheritance pattern in the Entity Framework, so all you have to do is create a `Person` class, change the `Instructor` and `Student` classes to derive from `Person`, add the new class to the `DbContext`, and create a migration. (For information about how to implement the other inheritance patterns, see Mapping the Table-Per-Type (TPT) Inheritance and Mapping the Table-Per-Concrete Class (TPC) Inheritance in the MSDN Entity Framework documentation.)

Create the Person class

In the *Models* folder, create *Person.cs* and replace the template code with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public abstract class Person
    {
        public int ID { get; set; }

        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }
    }
}
```

Update Instructor and Student

Now update the *Instructor.cs* and *Student.cs* to inherit values from the *Person.sc*.

In *Instructor.cs*, derive the `Instructor` class from the `Person` class and remove the key and name fields. The code will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public virtual ICollection<Course> Courses { get; set; }
        public virtual OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make similar changes to *Student.cs*. The `Student` class will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Add Person to the Model

In *SchoolContext.cs*, add a `DbSet` property for the `Person` entity type:

```
public DbSet<Person> People { get; set; }
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is updated, it will have a `Person` table in place of the `Student` and `Instructor` tables.

Create and Update Migrations

In the Package Manager Console (PMC), enter the following command:

```
Add-Migration Inheritance
```

Run the `Update-Database` command in the PMC. The command will fail at this point because we have existing data that migrations doesn't know how to handle. You get an error message like the following one:

> *Could not drop object 'dbo.Instructor' because it is referenced by a FOREIGN KEY constraint.*

Open *Migrations<timestamp>_Inheritance.cs* and replace the `Up` method with the following code:

```
public override void Up()
{
    // Drop foreign keys and indexes that point to tables we're going to drop.
    DropForeignKey("dbo.Enrollment", "StudentID", "dbo.Student");
    DropIndex("dbo.Enrollment", new[] { "StudentID" });

    RenameTable(name: "dbo.Instructor", newName: "Person");
    AddColumn("dbo.Person", "EnrollmentDate", c => c.DateTime());
    AddColumn("dbo.Person", "Discriminator", c => c.String(nullable: false, maxLength: 128, defaultValue:
"Instructor"));
    AlterColumn("dbo.Person", "HireDate", c => c.DateTime());
    AddColumn("dbo.Person", "OldId", c => c.Int(nullable: true));

    // Copy existing Student data into new Person table.
    Sql("INSERT INTO dbo.Person (LastName, FirstName, HireDate, EnrollmentDate, Discriminator, OldId) SELECT
LastName, FirstName, null AS HireDate, EnrollmentDate, 'Student' AS Discriminator, ID AS OldId FROM
dbo.Student");

    // Fix up existing relationships to match new PK's.
    Sql("UPDATE dbo.Enrollment SET StudentId = (SELECT ID FROM dbo.Person WHERE OldId = Enrollment.StudentId
AND Discriminator = 'Student')");

    // Remove temporary key
    DropColumn("dbo.Person", "OldId");

    DropTable("dbo.Student");

    // Re-create foreign keys and indexes pointing to new table.
    AddForeignKey("dbo.Enrollment", "StudentID", "dbo.Person", "ID", cascadeDelete: true);
    CreateIndex("dbo.Enrollment", "StudentID");
}
```

This code takes care of the following database update tasks:

- Removes foreign key constraints and indexes that point to the Student table.
- Renames the Instructor table as Person and makes changes needed for it to store Student data:
  - Adds nullable EnrollmentDate for students.
  - Adds Discriminator column to indicate whether a row is for a student or an instructor.
  - Makes HireDate nullable since student rows won't have hire dates.
  - Adds a temporary field that will be used to update foreign keys that point to students. When you copy students into the Person table they'll get new primary key values.
- Copies data from the Student table into the Person table. This causes students to get assigned new primary key values.
- Fixes foreign key values that point to students.
- Re-creates foreign key constraints and indexes, now pointing them to the Person table.

(If you had used GUID instead of integer as the primary key type, the student primary key values wouldn't have to change, and several of these steps could have been omitted.)

Run the `update-database` command again.

(In a production system you would make corresponding changes to the Down method in case you ever had to use that to go back to the previous database version. For this tutorial you won't be using the Down method.)

NOTE

It's possible to get other errors when migrating data and making schema changes. If you get migration errors you can't resolve, you can continue with the tutorial by changing the connection string in the *Web.config* file or by deleting the database. The simplest approach is to rename the database in the *Web.config* file. For example, change the database name to ContosoUniversity2 as shown in the following example:

```
<add name="SchoolContext"
    connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=ContosoUniversity2;Integrated
Security=SSPI;"
    providerName="System.Data.SqlClient" />
```

With a new database, there is no data to migrate, and the `update-database` command is much more likely to complete without errors. For instructions on how to delete the database, see How to Drop a Database from Visual Studio 2012. If you take this approach in order to continue with the tutorial, skip the deployment step at the end of this tutorial or deploy to a new site and database. If you deploy an update to the same site you've been deploying to already, EF will get the same error there when it runs migrations automatically. If you want to troubleshoot a migrations error, the best resource is one of the Entity Framework forums or StackOverflow.com.

Test the implementation

Run the site and try various pages. Everything works the same as it did before.

In **Server Explorer,** expand **Data Connections\SchoolContext** and then **Tables**, and you see that the **Student** and **Instructor** tables have been replaced by a **Person** table. Expand the **Person** table and you see that it has all of the columns that used to be in the **Student** and **Instructor** tables.

Right-click the Person table, and then click **Show Table Data** to see the discriminator column.

The following diagram illustrates the structure of the new School database:

Deploy to Azure

This section requires you to have completed the optional **Deploying the app to Azure** section in Part 3, Sorting, Filtering, and Paging of this tutorial series. If you had migrations errors that you resolved by deleting the database in your local project, skip this step; or create a new site and database, and deploy to the new environment.

1. In Visual Studio, right-click the project in **Solution Explorer** and select **Publish** from the context menu.
2. Click **Publish**.

   The Web app opens in your default browser.
3. Test the application to verify it's working.

   The first time you run a page that accesses the database, the Entity Framework runs all of the migrations `Up` methods required to bring the database up to date with the current data model.

For more information about this and other inheritance structures, see TPT Inheritance Pattern and TPH Inheritance Pattern on MSDN. In the next tutorial you'll see how to handle a variety of relatively advanced Entity Framework scenarios.

Next steps

In this tutorial, you:

- Learned to map inheritance to database
- Created the Person class
- Updated Instructor and Student
- Added Person to the Model
- Created and Update Migrations
- Tested the implementation
- Deployed to Azure

Advance to the next article to learn about topics that are useful to be aware of when you go beyond the basics of developing ASP.NET web applications that use Entity Framework Code First.

Advanced Entity Framework Scenarios

Tutorial: Learn about advanced EF Scenarios for an MVC 5 Web app

9/16/2020 • 17 minutes to read • Edit Online

In the previous tutorial you implemented table-per-hierarchy inheritance. This tutorial includes introduces several topics that are useful to be aware of when you go beyond the basics of developing ASP.NET web applications that use Entity Framework Code First. The first few sections have step-by-step instructions that walk you through the code and using Visual Studio to complete tasks The sections that follow introduce several topics with brief introductions followed by links to resources for more information.

For most of these topics, you'll work with pages that you already created. To use raw SQL to do bulk updates you'll create a new page that updates the number of credits of all courses in the database:

In this tutorial, you:

- Perform raw SQL queries
- Perform no-tracking queries
- Examine SQL queries sent to database

You also learn about:

- Creating an abstraction layer
- Proxy classes
- Automatic change detection
- Automatic validation
- Entity Framework Power Tools
- Entity Framework source code

Prerequisite

- Implementing Inheritance

Perform raw SQL queries

The Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options:

- Use the DbSet.SqlQuery method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they are automatically tracked by the database context unless you turn tracking off. (See the following section about the AsNoTracking method.)
- Use the Database.SqlQuery method for queries that return types that aren't entities. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.
- Use the Database.ExecuteSqlCommand for non-query commands.

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created, and these methods make it possible for you to handle such exceptions.

As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Calling a Query that Returns Entities

The DbSet<TEntity> class provides a method that you can use to execute a query that returns an entity of type `TEntity`. To see how this works you'll change the code in the `Details` method of the `Department` controller.

In *DepartmentController.cs*, in the `Details` method, replace the `db.Departments.FindAsync` method call with a `db.Departments.SqlQuery` method call, as shown in the following highlighted code:

```
public async Task<ActionResult> Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }

    // Commenting out original code to show how to use a raw SQL query.
    //Department department = await db.Departments.FindAsync(id);

    // Create and execute raw SQL query.
    string query = "SELECT * FROM Department WHERE DepartmentID = @p0";
    Department department = await db.Departments.SqlQuery(query, id).SingleOrDefaultAsync();

    if (department == null)
    {
        return HttpNotFound();
    }
    return View(department);
}
```

To verify that the new code works correctly, select the **Departments** tab and then **Details** for one of the departments. Make sure all of the data displays as expected.

Calling a Query that Returns Other Types of Objects

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. The code that does this in *HomeController.cs* uses LINQ:

```
var data = from student in db.Students
           group student by student.EnrollmentDate into dateGroup
           select new EnrollmentDateGroup()
           {
               EnrollmentDate = dateGroup.Key,
               StudentCount = dateGroup.Count()
           };
```

Suppose you want to write the code that retrieves this data directly in SQL rather than using LINQ. To do that you need to run a query that returns something other than entity objects, which means you need to use the Database.SqlQuery method.

In *HomeController.cs*, replace the LINQ statement in the `About` method with a SQL statement, as shown in the following highlighted code:

```
public ActionResult About()
{
    // Commenting out LINQ to show how to do the same thing in SQL.
    //IQueryable<EnrollmentDateGroup> = from student in db.Students
    //           group student by student.EnrollmentDate into dateGroup
    //           select new EnrollmentDateGroup()
    //           {
    //               EnrollmentDate = dateGroup.Key,
    //               StudentCount = dateGroup.Count()
    //           };

    // SQL version of the above LINQ code.
    string query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount "
        + "FROM Person "
        + "WHERE Discriminator = 'Student' "
        + "GROUP BY EnrollmentDate";
    IEnumerable<EnrollmentDateGroup> data = db.Database.SqlQuery<EnrollmentDateGroup>(query);

    return View(data.ToList());
}
```

Run the About page. Verify that it displays the same data it did before.

Calling an Update Query

Suppose Contoso University administrators want to be able to perform bulk changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that enables the user to specify a factor by which to change the number of credits for all courses, and you'll make the change by executing a SQL `UPDATE` statement.

In *CourseController.cs*, add `UpdateCourseCredits` methods for `HttpGet` and `HttpPost`:

```
public ActionResult UpdateCourseCredits()
{
    return View();
}

[HttpPost]
public ActionResult UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewBag.RowsAffected = db.Database.ExecuteSqlCommand("UPDATE Course SET Credits = Credits * {0}",
multiplier);
    }
    return View();
}
```

When the controller processes an `HttpGet` request, nothing is returned in the `ViewBag.RowsAffected` variable, and the view displays an empty text box and a submit button.

When the **Update** button is clicked, the `HttpPost` method is called, and `multiplier` has the value entered in the text box. The code then executes the SQL that updates courses and returns the number of affected rows to the view in the `ViewBag.RowsAffected` variable. When the view gets a value in that variable, it displays the number of rows updated instead of the text box and submit button.

In *CourseController.cs*, right-click one of the `UpdateCourseCredits` methods, and then click **Add View**. The **Add View** dialog appears. Leave the defaults and select **Add**.

In *Views\Course\UpdateCourseCredits.cshtml*, replace the template code with the following code:

```
@model ContosoUniversity.Models.Course

@{
    ViewBag.Title = "UpdateCourseCredits";
}

<h2>Update Course Credits</h2>

@if (ViewBag.RowsAffected == null)
{
    using (Html.BeginForm())
    {
        <p>
            Enter a number to multiply every course's credits by: @Html.TextBox("multiplier")
        </p>
        <p>
            <input type="submit" value="Update" />
        </p>
    }
}
@if (ViewBag.RowsAffected != null)
{
    <p>
        Number of rows updated: @ViewBag.RowsAffected
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:50205/Course/UpdateCourseCredits`). Enter a number in the text box:

Click **Update**. You see the number of rows affected.

Click **Back to List** to see the list of courses with the revised number of credits.

For more information about raw SQL queries, see Raw SQL Queries on MSDN.

No-tracking queries

When a database context retrieves table rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can disable tracking of entity objects in memory by using the AsNoTracking method. Typical scenarios in which you might want to do that include the following:

- A query retrieves such a large volume of data that turning off tracking might noticeably enhance performance.
- You want to attach an entity in order to update it, but you earlier retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to handle this situation is to use the `AsNoTracking` option with the earlier query.

For an example that demonstrates how to use the AsNoTracking method, see the earlier version of this tutorial. This version of the tutorial doesn't set the Modified flag on a model-binder-created entity in the Edit method, so it doesn't need `AsNoTracking`.

Examine SQL sent to database

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. In an earlier tutorial you saw how to do that in interceptor code; now you'll see some ways to do it without writing interceptor code. To try this out, you'll look at a simple query and then look at what happens to it as you add options such eager loading, filtering, and sorting.

In *Controllers/CourseController*, replace the `Index` method with the following code, in order to temporarily stop eager loading:

```
public ActionResult Index()
{
    var courses = db.Courses;
    var sql = courses.ToString();
    return View(courses.ToList());
}
```

Now set a breakpoint on the `return` statement (F9 with the cursor on that line). Press **F5** to run the project in debug mode, and select the Course Index page. When the code reaches the breakpoint, examine the `sql` variable. You see the query that's sent to SQL Server. It's a simple `Select` statement.

```
{SELECT
[Extent1].[CourseID] AS [CourseID],
[Extent1].[Title] AS [Title],
[Extent1].[Credits] AS [Credits],
[Extent1].[DepartmentID] AS [DepartmentID]
FROM [Course] AS [Extent1]}
```

Click the magnifying glass to see the query in the **Text Visualizer**.

Now you'll add a drop-down list to the Courses Index page so that users can filter for a particular department. You'll sort the courses by title, and you'll specify eager loading for the `Department` navigation property.

In *CourseController.cs*, replace the `Index` method with the following code:

```
public ActionResult Index(int? SelectedDepartment)
{
    var departments = db.Departments.OrderBy(q => q.Name).ToList();
    ViewBag.SelectedDepartment = new SelectList(departments, "DepartmentID", "Name", SelectedDepartment);
    int departmentID = SelectedDepartment.GetValueOrDefault();

    IQueryable<Course> courses = db.Courses
        .Where(c => !SelectedDepartment.HasValue || c.DepartmentID == departmentID)
        .OrderBy(d => d.CourseID)
        .Include(d => d.Department);
    var sql = courses.ToString();
    return View(courses.ToList());
}
```

Restore the breakpoint on the `return` statement.

The method receives the selected value of the drop-down list in the `SelectedDepartment` parameter. If nothing is selected, this parameter will be null.

A `SelectList` collection containing all departments is passed to the view for the drop-down list. The parameters passed to the `SelectList` constructor specify the value field name, the text field name, and the selected item.

For the `Get` method of the `Course` repository, the code specifies a filter expression, a sort order, and eager loading for the `Department` navigation property. The filter expression always returns `true` if nothing is selected in the drop-down list (that is, `SelectedDepartment` is null).

In *Views\Course\Index.cshtml*, immediately before the opening `table` tag, add the following code to create the drop-down list and a submit button:

```
@using (Html.BeginForm())
{
    <p>Select Department: @Html.DropDownList("SelectedDepartment","All")
    <input type="submit" value="Filter" /></p>
}
```

With the breakpoint still set, run the Course Index page. Continue through the first times that the code hits a breakpoint, so that the page is displayed in the browser. Select a department from the drop-down list and click **Filter**.

This time the first breakpoint will be for the departments query for the drop-down list. Skip that and view the `query` variable the next time the code reaches the breakpoint in order to see what the `Course` query now looks like. You'll see something like the following:

```
SELECT
    [Project1].[CourseID] AS [CourseID],
    [Project1].[Title] AS [Title],
    [Project1].[Credits] AS [Credits],
    [Project1].[DepartmentID] AS [DepartmentID],
    [Project1].[DepartmentID1] AS [DepartmentID1],
    [Project1].[Name] AS [Name],
    [Project1].[Budget] AS [Budget],
    [Project1].[StartDate] AS [StartDate],
    [Project1].[InstructorID] AS [InstructorID],
    [Project1].[RowVersion] AS [RowVersion]
    FROM ( SELECT
        [Extent1].[CourseID] AS [CourseID],
        [Extent1].[Title] AS [Title],
        [Extent1].[Credits] AS [Credits],
        [Extent1].[DepartmentID] AS [DepartmentID],
        [Extent2].[DepartmentID] AS [DepartmentID1],
        [Extent2].[Name] AS [Name],
        [Extent2].[Budget] AS [Budget],
        [Extent2].[StartDate] AS [StartDate],
        [Extent2].[InstructorID] AS [InstructorID],
        [Extent2].[RowVersion] AS [RowVersion]
        FROM  [dbo].[Course] AS [Extent1]
        INNER JOIN [dbo].[Department] AS [Extent2] ON [Extent1].[DepartmentID] = [Extent2].[DepartmentID]
        WHERE @p__linq__0 IS NULL OR [Extent1].[DepartmentID] = @p__linq__1
    )  AS [Project1]
    ORDER BY [Project1].[CourseID] ASC
```

You can see that the query is now a `JOIN` query that loads `Department` data along with the `Course` data, and that it includes a `WHERE` clause.

Remove the `var sql = courses.ToString()` line.

Create an abstraction layer

Many developers write code to implement the repository and unit of work patterns as a wrapper around code that works with the Entity Framework. These patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD). However, writing additional code to implement these patterns is not always the best choice for applications that use EF, for several reasons:

- The EF context class itself insulates your code from data-store-specific code.
- The EF context class can act as a unit-of-work class for database updates that you do using EF.
- Features introduced in Entity Framework 6 make it easier to implement TDD without writing repository code.

For more information about how to implement the repository and unit of work patterns, see the Entity Framework 5 version of this tutorial series. For information about ways to implement TDD in Entity Framework 6, see the following resources:

- How EF6 Enables Mocking DbSets more easily
- Testing with a mocking framework
- Testing with your own test doubles

Proxy classes

When the Entity Framework creates entity instances (for example, when you execute a query), it often creates them as instances of a dynamically generated derived type that acts as a proxy for the entity. For example, see the following two debugger images. In the first image, you see that the `student` variable is the expected `Student`

type immediately after you instantiate the entity. In the second image, after EF has been used to read a student entity from the database, you see the proxy class.

This proxy class overrides some virtual properties of the entity to insert hooks for performing actions automatically when the property is accessed. One function this mechanism is used for is lazy loading.

Most of the time you don't need to be aware of this use of proxies, but there are exceptions:

- In some scenarios you might want to prevent the Entity Framework from creating proxy instances. For example, when you're serializing entities you generally want the POCO classes, not the proxy classes. One way to avoid serialization problems is to serialize data transfer objects (DTOs) instead of entity objects, as shown in the Using Web API with Entity Framework tutorial. Another way is to disable proxy creation.
- When you instantiate an entity class using the `new` operator, you don't get a proxy instance. This means you don't get functionality such as lazy loading and automatic change tracking. This is typically okay; you generally don't need lazy loading, because you're creating a new entity that isn't in the database, and you generally don't need change tracking if you're explicitly marking the entity as `Added`. However, if you do need lazy loading and you need change tracking, you can create new entity instances with proxies using the Create method of the `DbSet` class.
- You might want to get an actual entity type from a proxy type. You can use the GetObjectType method of the `ObjectContext` class to get the actual entity type of a proxy type instance.

For more information, see Working with Proxies on MSDN.

Automatic change detection

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity is queried or attached. Some of the methods that cause automatic change detection are the following:

- `DbSet.Find`
- `DbSet.Local`
- `DbSet.Remove`
- `DbSet.Add`
- `DbSet.Attach`
- `DbContext.SaveChanges`
- `DbContext.GetValidationErrors`
- `DbContext.Entry`
- `DbChangeTracker.Entries`

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the AutoDetectChangesEnabled property. For more information, see Automatically Detecting Changes on MSDN.

Automatic validation

When you call the `SaveChanges` method, by default the Entity Framework validates the data in all properties of all changed entities before updating the database. If you've updated a large number of entities and you've already validated the data, this work is unnecessary and you could make the process of saving the changes take less time by temporarily turning off validation. You can do that using the ValidateOnSaveEnabled property. For more information, see Validation on MSDN.

Entity Framework Power Tools

Entity Framework Power Tools is a Visual Studio add-in that was used to create the data model diagrams shown in these tutorials. The tools can also do other function such as generate entity classes based on the tables in an existing database so that you can use the database with Code First. After you install the tools, some additional options appear in context menus. For example, when you right-click your context class in **Solution Explorer**, you see and **Entity Framework** option. This gives you the ability to generate a diagram. When you're using Code First you can't change the data model in the diagram, but you can move things around to make it easier to understand.

Entity Framework source code

The source code for Entity Framework 6 is available at GitHub. You can file bugs, and you can contribute your own enhancements to the EF source code.

Although the source code is open, Entity Framework is fully supported as a Microsoft product. The Microsoft Entity Framework team keeps control over which contributions are accepted and tests all code changes to ensure the quality of each release.

Acknowledgments

- Tom Dykstra wrote the original version of this tutorial, co-authored the EF 5 update, and wrote the EF 6 update. Tom is a senior programming writer on the Microsoft Web Platform and Tools Content Team.
- Rick Anderson (twitter @RickAndMSFT) did most of the work updating the tutorial for EF 5 and MVC 4 and co-authored the EF 6 update. Rick is a senior programming writer for Microsoft focusing on Azure and MVC.
- Rowan Miller and other members of the Entity Framework team assisted with code reviews and helped debug

many issues with migrations that arose while we were updating the tutorial for EF 5 and EF 6.

Troubleshoot common errors

Cannot create/shadow copy

Error Message:

> Cannot create/shadow copy '<filename>' when that file already exists.

Solution

Wait a few seconds and refresh the page.

Update-Database not recognized

Error Message (from the `Update-Database` command in the PMC):

> The term 'Update-Database' is not recognized as the name of a cmdlet, function, script file, or operable program. Check the spelling of the name, or if a path was included, verify that the path is correct and try again.

Solution

Exit Visual Studio. Reopen project and try again.

Validation failed

Error Message (from the `Update-Database` command in the PMC):

> Validation failed for one or more entities. See 'EntityValidationErrors' property for more details.

Solution

One cause of this problem is validation errors when the `Seed` method runs. See Seeding and Debugging Entity Framework (EF) DBs for tips on debugging the `Seed` method.

HTTP 500.19 error

Error Message:

> HTTP Error 500.19 - Internal Server Error The requested page cannot be accessed because the related configuration data for the page is invalid.

Solution

One way you can get this error is from having multiple copies of the solution, each of them using the same port number. You can usually solve this problem by exiting all instances of Visual Studio, then restarting the project you're working on. If that doesn't work, try changing the port number. Right click on the project file and then click properties. Select the **Web** tab and then change the port number in the **Project Url** text box.

Error locating SQL Server instance

Error Message:

> A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution

Check the connection string. If you have manually deleted the database, change the name of the database in the construction string.

Get the code

Additional resources

For more information about how to work with data using the Entity Framework, see the EF documentation page on MSDN and ASP.NET Data Access - Recommended Resources.

For more information about how to deploy your web application after you've built it, see ASP.NET Web Deployment - Recommended Resources in the MSDN Library.

For information about other topics related to MVC, such as authentication and authorization, see the ASP.NET MVC - Recommended Resources.

Next steps

In this tutorial, you:

- Performed raw SQL queries
- Performed no-tracking queries
- Examined SQL queries sent to the database

You also learned about:

- Creating an abstraction layer
- Proxy classes
- Automatic change detection
- Automatic validation
- Entity Framework Power Tools
- Entity Framework source code

This completes this series of tutorials on using the Entity Framework in an ASP.NET MVC application. If you want to learn about EF Database First, see the DB First tutorial series.

- Enhancing Data Validation

Tutorial: Get started with EF Database First using MVC 5

2/20/2020 • 6 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table. In the last part of the series, you learn how add data annotations to the data model to specify validation requirements and display formatting. When you're done, you can advance to an Azure article to learn how to deploy a .NET app and SQL database to Azure App Service.

This tutorial shows how to start with an existing database and quickly create a web application that enables users to interact with the data. It uses the Entity Framework 6 and MVC 5 to build the web application. The ASP.NET Scaffolding feature enables you to automatically generate code for displaying, updating, creating and deleting data. Using the publishing tools within Visual Studio, you can easily deploy the site and database to Azure.

This part of the series focuses on creating a database and populating it with data.

This series was written with contributions from Tom Dykstra and Rick Anderson. It was improved based on feedback from users in the comments section.

In this tutorial, you:

- Set up the database

Prerequisites

Visual Studio 2017

Set up the database

To mimic the environment of having an existing database, you will first create a database with some pre-filled data, and then create your web application that connects to the database.

This tutorial was developed using LocalDB with Visual Studio 2017. You can use an existing database server instead of LocalDB, but depending on your version of Visual Studio and your type of database, all of the data tools in Visual Studio might not be supported. If the tools are not available for your database, you may need to perform some of the database-specific steps within the management suite for your database.

If you have a problem with the database tools in your version of Visual Studio, make sure you have installed the latest version of the database tools. For information about updating or installing the database tools, see Microsoft SQL Server Data Tools.

Launch Visual Studio and create a **SQL Server Database Project**. Name the project **ContosoUniversityData**.

You now have an empty database project. To make sure that you can deploy this database to Azure, you'll set Azure SQL Database as the target platform for the project. Setting the target platform does not actually deploy the database; it only means that the database project will verify that the database design is compatible with the target platform. To set the target platform, open the **Properties** for the project and select **Microsoft Azure SQL Database** for the target platform.

You can create the tables needed for this tutorial by adding SQL scripts that define the tables. Right-click your project and add a new item. Select **Tables and Views** > **Table** and name it *Student*.

In the table file, replace the T-SQL command with the following code to create the table.

```
CREATE TABLE [dbo].[Student] (
    [StudentID]      INT           IDENTITY (1, 1) NOT NULL,
    [LastName]       NVARCHAR (50) NULL,
    [FirstName]      NVARCHAR (50) NULL,
    [EnrollmentDate] DATETIME      NULL,
    PRIMARY KEY CLUSTERED ([StudentID] ASC)
)
```

Notice that the design window automatically synchronizes with the code. You can work with either the code or designer.

Add another table. This time name it Course and use the following T-SQL command.

```
CREATE TABLE [dbo].[Course] (
    [CourseID] INT           IDENTITY (1, 1) NOT NULL,
    [Title]    NVARCHAR (50) NULL,
    [Credits]  INT           NULL,
    PRIMARY KEY CLUSTERED ([CourseID] ASC)
)
```

And, repeat one more time to create a table named Enrollment.

```
CREATE TABLE [dbo].[Enrollment] (
    [EnrollmentID] INT IDENTITY (1, 1) NOT NULL,
    [Grade]        DECIMAL(3, 2) NULL,
    [CourseID]     INT NOT NULL,
    [StudentID]    INT NOT NULL,
    PRIMARY KEY CLUSTERED ([EnrollmentID] ASC),
    CONSTRAINT [FK_dbo.Enrollment_dbo.Course_CourseID] FOREIGN KEY ([CourseID])
        REFERENCES [dbo].[Course] ([CourseID]) ON DELETE CASCADE,
    CONSTRAINT [FK_dbo.Enrollment_dbo.Student_StudentID] FOREIGN KEY ([StudentID])
        REFERENCES [dbo].[Student] ([StudentID]) ON DELETE CASCADE
)
```

You can populate your database with data through a script that is run after the database is deployed. Add a Post-Deployment Script to the project. Right-click your project and add a new item. Select **User Scripts** > **Post-Deployment Script**. You can use the default name.

Add the following T-SQL code to the post-deployment script. This script simply adds data to the database when no matching record is found. It does not overwrite or delete any data you may have entered into the database.

```
MERGE INTO Course AS Target
USING (VALUES
        (1, 'Economics', 3),
        (2, 'Literature', 3),
        (3, 'Chemistry', 4)
)
AS Source (CourseID, Title, Credits)
ON Target.CourseID = Source.CourseID
WHEN NOT MATCHED BY TARGET THEN
INSERT (Title, Credits)
VALUES (Title, Credits);

MERGE INTO Student AS Target
USING (VALUES
        (1, 'Tibbetts', 'Donnie', '2013-09-01'),
        (2, 'Guzman', 'Liza', '2012-01-13'),
(3, 'Catlett', 'Phil', '2011-09-03')
)
AS Source (StudentID, LastName, FirstName, EnrollmentDate)
ON Target.StudentID = Source.StudentID
WHEN NOT MATCHED BY TARGET THEN
INSERT (LastName, FirstName, EnrollmentDate)
VALUES (LastName, FirstName, EnrollmentDate);

MERGE INTO Enrollment AS Target
USING (VALUES
(1, 2.00, 1, 1),
(2, 3.50, 1, 2),
(3, 4.00, 2, 3),
(4, 1.80, 2, 1),
(5, 3.20, 3, 1),
(6, 4.00, 3, 2)
)
AS Source (EnrollmentID, Grade, CourseID, StudentID)
ON Target.EnrollmentID = Source.EnrollmentID
WHEN NOT MATCHED BY TARGET THEN
INSERT (Grade, CourseID, StudentID)
VALUES (Grade, CourseID, StudentID);
```

It is important to note that the post-deployment script is run every time you deploy your database project. Therefore, you need to carefully consider your requirements when writing this script. In some cases, you may wish to start over from a known set of data every time the project is deployed. In other cases, you may not want to alter the existing data in any way. Based on your requirements, you can decide whether you need a post-deployment script or what you need to include in the script. For more information about populating your database with a post-deployment script, see Including Data in a SQL Server Database Project.

You now have 4 SQL script files but no actual tables. You are ready to deploy your database project to localdb. In Visual Studio, click the Start button (or F5) to build and deploy your database project. Check the **Output** tab to verify that the build and deployment succeeded.

To see that the new database has been created, open **SQL Server Object Explorer** and look for the name of the project in the correct local database server (in this case **(localdb)\ProjectsV13**).

To see that the tables are populated with data, right-click a table, and select **View Data**.

An editable view of the table data is displayed. For example, if you select **Tables** > **dbo.course** > **View Data**, you see a table with three columns (**Course**, **Title**, and **Credits**) and four rows.

Additional resources

For an introductory example of Code First development, see Getting Started with ASP.NET MVC 5. For a more advanced example, see Creating an Entity Framework Data Model for an ASP.NET MVC 4 App.

For guidance on selecting which Entity Framework approach to use, see Entity Framework Development Approaches.

Next steps

In this tutorial, you:

- Set up the database

Advance to the next tutorial to learn how to create the web application and data models.

Create the web application and data models

Tutorial: Create the Web Application and Data Models for EF Database First with ASP.NET MVC

2/20/2020 • 3 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table.

This tutorial focuses on creating the web application, and generating the data models based on your database tables.

In this tutorial, you:

- Create an ASP.NET web app
- Generate the models

Prerequisites

- Getting started with Entity Framework 6 Database First using MVC 5

Create an ASP.NET web app

In either a new solution or the same solution as the database project, create a new project in Visual Studio and select the **ASP.NET Web Application** template. Name the project **ContosoSite**.

Click **OK**.

In the New ASP.NET Project window, select the **MVC** template. You can clear the **Host in the cloud** option for now because you will deploy the application to the cloud later. Click **OK** to create the application.

The project is created with the default files and folders.

In this tutorial, you will use Entity Framework 6. You can double-check the version of Entity Framework in your

project through the Manage NuGet Packages window. If necessary, update your version of Entity Framework.

Generate the models

You will now create Entity Framework models from the database tables. These models are classes that you will use to work with the data. Each model mirrors a table in the database and contains properties that correspond to the columns in the table.

Right-click the **Models** folder, and select **Add** and **New Item**.

In the Add New Item window, select **Data** in the left pane and **ADO.NET Entity Data Model** from the options in the center pane. Name the new model file **ContosoModel**.

Click **Add**.

In the Entity Data Model Wizard, select **EF Designer from database**.

Click **Next**.

If you have database connections defined within your development environment, you may see one of these connections pre-selected. However, you want to create a new connection to the database you created in the first part of this tutorial. Click the **New Connection** button.

In the Connection Properties window, provide the name of the local server where your database was created (in this case **(localdb)\ProjectsV13**). After providing the server name, select the ContosoUniversityData from the available databases.

Click **OK**.

The correct connection properties are now displayed. You can use the default name for connection in the Web.Config file.

Click **Next**.

Select the latest version of Entity Framework.

Click **Next**.

Select **Tables** to generate models for all three tables.

Click **Finish**.

If you receive a security warning, select **OK** to continue running the template.

The models are generated from the database tables, and a diagram is displayed that shows the properties and relationships between the tables.

The Models folder now includes many new files related to the models that were generated from the database.

The **ContosoModel.Context.cs** file contains a class that derives from the **DbContext** class, and provides a property for each model class that corresponds to a database table. The **Course.cs**, **Enrollment.cs**, and **Student.cs** files contain the model classes that represent the databases tables. You will use both the context class and the model classes when working with scaffolding.

Before proceeding with this tutorial, build the project. In the next section, you will generate code based on the data models, but that section will not work if the project has not been built.

Next steps

In this tutorial, you:

- Created an ASP.NET web app
- Generated the models

Advance to the next tutorial to learn how to create generate code based on the data models.

Generating views

Tutorial: Generate views for EF Database First with ASP.NET MVC app

2/20/2020 • 4 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table.

This tutorial focuses on using ASP.NET Scaffolding to generate the controllers and views.

In this tutorial, you:

- Add scaffold
- Add links to new views
- Display student views
- Display enrollment views

Prerequisite

- Create the web application and data models

Add scaffold

You are ready to generate code that will provide standard data operations for the model classes. You add the code by adding a scaffold item. There are many options for the type of scaffolding you can add; in this tutorial, the scaffold will include a controller and views that correspond to the Student and Enrollment models you created in the previous section.

To maintain consistency in your project, you will add the new controller to the existing **Controllers** folder. Right-click the **Controllers** folder, and select **Add** > **New Scaffolded Item**.

Select the **MVC 5 Controller with views, using Entity Framework** option. This option will generate the controller and views for updating, deleting, creating and displaying the data in your model.

Select **Student (ContosoSite.Models)** for the model class and select the **ContosoUniversityDataEntities (ContosoSite.Models)** for the context class. Keep the controller name as **StudentsController**.

Click **Add**.

If you receive an error, it may be because you did not build the project in the previous section. If so, try building the project, and then add the scaffolded item again.

After the code generation process is complete, you will see a new controller and views in your project's **Controllers** and **Views** > **Students** folders.

Perform the same steps again, but add a scaffold for the **Enrollment** class. When finished, you have an **EnrollmentsController.cs** file, and a folder under **Views** named **Enrollments** with the Create, Delete, Details, Edit and Index views.

Add links to new views

To make it easier for you to navigate to your new views, you can add a couple of hyperlinks to the Index views for students and enrollments. Open the file at **Views** > **Home** > *Index.cshtml*, which is the home page for your site. Add the following code below the jumbotron.

```
<div>
    @Html.ActionLink("List of students", "Index", "Students")<br />
    @Html.ActionLink("List of enrollments", "Index", "Enrollments")
</div>
```

For the ActionLink method, the first parameter is the text to display in the link. The second parameter is the action and the third parameter is the name of the controller. For example, the first link points to the Index action in StudentsController. The actual hyperlink is constructed from these values. The first link ultimately takes users to the **Index.cshtml** file within the **Views/Students** folder.

Display student views

You will verify that the code added to your project correctly displays a list of the students, and enables users to edit, create, or delete the student records in the database.

Right-click the **Views** > **Home** > *Index.cshtml* file, and select **View in Browser**. On the application home page, select **List of students**.

On the **Index** page, notice the list of the students and links to modify this data. Select the **Create New** link and provide some values for a new student. Click **Create**, and notice the new student is added to your list.

Back on the **Index** page, select the **Edit** link, and change some of the values for a student. Click **Save**, and notice the student record has been changed.

Finally, select the **Delete** link and confirm that you want to delete the record by clicking the **Delete** button.

Without writing any code, you have added views that perform common operations on the data in the Student table.

You may have noticed that the text label for a field is based on the database property (such as **LastName**) which is not necessarily what you want to display on the web page. For example, you may prefer the label to be **Last Name**. You will fix this display issue later in the tutorial.

Display enrollment views

Your database includes a one-to-many relationship between the Student and Enrollment tables, and a one-to-many relationship between the Course and Enrollment tables. The views for Enrollment correctly handle these relationships. Navigate to the home page for your site and select the **List of enrollments** link and then the **Create New** link.

The view displays a form for creating a new enrollment record. In particular, notice that the form contains a **CourseID** drop-down list and a **StudentID** drop-down list. Both are populated with values from the related tables.

Furthermore, validation of the provided values is automatically applied based on the data type of the field. **Grade** requires a number, so an error message is displayed if you try to provide an incompatible value: *The field Grade*

must be a number.

You have verified that the automatically-generated views enable users to work with the data in the database. In the next tutorial in this series, you will update the database and make the corresponding changes in the web application.

Next steps

In this tutorial, you:

- Added scaffold
- Added links to new views
- Displayed student views
- Displayed enrollment views

Advance to the next tutorial to learn how to change the database.

Change the database

Tutorial: Change the database for EF Database First with ASP.NET MVC app

2/20/2020 • 2 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table.

This tutorial focuses on making an update to the database structure and propagating that change throughout the web application.

In this tutorial, you:

- Add a column
- Add the property to the views

Prerequisites

- Generating views

Add a column

If you update the structure of a table in your database, you need to ensure that your change is propagated to the data model, views, and controller.

For this tutorial, you will add a new column to the Student table to record the middle name of the student. To add this column, open the database project, and open the Student.sql file. Through either the designer or the T-SQL code, add a column named **MiddleName** that is an NVARCHAR(50) and allows NULL values.

Deploy this change to your local database by starting your database project (or F5). The new field is added to the table. If you do not see it in the SQL Server Object Explorer, click the Refresh button in the pane.

The new column exists in the database table, but it does not currently exist in the data model class. You must update the model to include your new column. In the **Models** folder, open the **ContosoModel.edmx** file to

display the model diagram. Notice that the Student model does not contain the MiddleName property. Right-click anywhere on the design surface, and select **Update Model from Database**.

In the Update Wizard, select the **Refresh** tab and then select **Tables** > **dbo** > **Student**. Click **Finish**.

After the update process is finished, the database diagram includes the new **MiddleName** property. Save the **ContosoModel.edmx** file. You must save this file for the new property to be propagated to the **Student.cs** class. You have now updated the database and the model.

Build the solution.

Add the property to the views

Unfortunately, the views still do not contain the new property. To update the views you have two options - you can either re-generate the views by once again adding scaffolding for the Student class, or you can manually add the new property to your existing views. In this tutorial, you will add the scaffolding again because you have not made any customized changes to the automatically-generated views. You might consider manually adding the property when you have made changes to the views and do not want to lose those changes.

To ensure the views are re-created, delete the **Students** folder under **Views**, and delete the **StudentsController**. Then, right-click the **Controllers** folder and add scaffolding for the **Student** model. Again, name the controller **StudentsController**. Select **Add**.

Build the solution again. The views now contain the MiddleName property.

Next steps

In this tutorial, you:

- Added a column
- Added the property to the views

Advance to the next tutorial to learn how to customize the view for showing details about a student record.

Customize a view

Tutorial: Customize view for EF Database First with ASP.NET MVC app

2/20/2020 • 2 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table.

This tutorial focuses on changing the automatically-generated views to enhance the presentation.

In this tutorial, you:

- Add courses to the student detail page
- Confirm that the courses are added to the page

Prerequisites

- Change the database

Add courses to student detail

The generated code provides a good starting point for your application but it does not necessarily provide all of the functionality that you need in your application. You can customize the code to meet the particular requirements of your application. Currently, your application does not display the enrolled courses for the selected student. In this section, you will add the enrolled courses for each student to the **Details** view for the student.

Open **Views** > **Students** > *Details.cshtml*. Below the last </dl> tag, but before the closing tag, add the following code.

```
<table class="table">
    <tr>
        <th>
            Course Title
        </th>
        <th>
            Grade
        </th>
        <th>
            Credits
        </th>
    </tr>

    @foreach (var item in Model.Enrollments)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.Course.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Grade)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Course.Credits)
            </td>
        </tr>
    }
</table>
```

This code creates a table that displays a row for each record in the Enrollment table for the selected student. The **Display** method renders HTML for the object (modelItem) that represents the expression. You use the Display method (rather than simply embedding the property value in the code) to make sure the value is formatted correctly based on its type and the template for that type. In this example, each expression returns a single property from the current record in the loop, and the values are primitive types which are rendered as text.

Confirm courses are added

Run the solution. Click **List of students** and select **Details** for one of the students. You will see the enrolled courses have been included in the view.

Next steps

In this tutorial, you:

- Added courses to the student detail page
- Confirmed that the courses are added to the page

Advance to the next tutorial to learn how to add data annotations to specify validation requirements and display formatting.

Enhance data validation

Tutorial: Enhance data validation for EF Database First with ASP.NET MVC app

2/20/2020 • 5 minutes to read • Edit Online

Using MVC, Entity Framework, and ASP.NET Scaffolding, you can create a web application that provides an interface to an existing database. This tutorial series shows you how to automatically generate code that enables users to display, edit, create, and delete data that resides in a database table. The generated code corresponds to the columns in the database table.

This tutorial focuses on adding data annotations to the data model to specify validation requirements and display formatting. It was improved based on feedback from users in the comments section.

In this tutorial, you:

- Add data annotations
- Add metadata classes

Prerequisites

- Customize a view

Add data annotations

As you saw in an earlier topic, some data validation rules are automatically applied to the user input. For example, you can only provide a number for the Grade property. To specify more data validation rules, you can add data annotations to your model class. These annotations are applied throughout your web application for the specified property. You can also apply formatting attributes that change how the properties are displayed; such as, changing the value used for text labels.

In this tutorial, you will add data annotations to restrict the length of the values provided for the FirstName, LastName, and MiddleName properties. In the database, these values are limited to 50 characters; however, in your web application that character limit is currently not enforced. If a user provides more than 50 characters for one of those values, the page will crash when attempting to save the value to the database. You will also restrict Grade to values between 0 and 4.

Select **Models** > **ContosoModel.edmx** > **ContosoModel.tt** and open the *Student.cs* file. Add the following highlighted code to the class.

```
namespace ContosoSite.Models
{
    using System;
    using System.Collections.Generic;
    using System.ComponentModel.DataAnnotations;

    public partial class Student
    {
        public Student()
        {
            this.Enrollments = new HashSet<Enrollment>();
        }

        public int StudentID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        public string FirstName { get; set; }
        public Nullable<System.DateTime> EnrollmentDate { get; set; }
        [StringLength(50)]
        public string MiddleName { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Open *Enrollment.cs* and add the following highlighted code.

```
namespace ContosoSite.Models
{
    using System;
    using System.Collections.Generic;
    using System.ComponentModel.DataAnnotations;

    public partial class Enrollment
    {
        public int EnrollmentID { get; set; }
        [Range(0, 4)]
        public Nullable<decimal> Grade { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }

        public virtual Course Course { get; set; }
        public virtual Student Student { get; set; }
    }
}
```

Build the solution.

Click **List of students** and select **Edit**. If you attempt to enter more than 50 characters, an error message is displayed.

Go back to the home page. Click **List of enrollments** and select **Edit**. Attempt to provide a grade above 4. You will receive this error: *The field Grade must be between 0 and 4.*

Add metadata classes

Adding the validation attributes directly to the model class works when you do not expect the database to change; however, if your database changes and you need to regenerate the model class, you will lose all of the attributes you had applied to the model class. This approach can be very inefficient and prone to losing important validation rules.

To avoid this problem, you can add a metadata class that contains the attributes. When you associate the model class to the metadata class, those attributes are applied to the model. In this approach, the model class can be regenerated without losing all of the attributes that have been applied to the metadata class.

In the **Models** folder, add a class named *Metadata.cs*.

Replace the code in *Metadata.cs* with the following code.

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoSite.Models
{
    public class StudentMetadata
    {
        [StringLength(50)]
        [Display(Name="Last Name")]
        public string LastName;

        [StringLength(50)]
        [Display(Name="First Name")]
        public string FirstName;

        [StringLength(50)]
        [Display(Name="Middle Name")]
        public string MiddleName;

        [Display(Name = "Enrollment Date")]
        public Nullable<System.DateTime> EnrollmentDate;
    }

    public class EnrollmentMetadata
    {
        [Range(0, 4)]
        public Nullable<decimal> Grade;
    }
}
```

These metadata classes contain all of the validation attributes that you had previously applied to the model classes. The **Display** attribute is used to change the value used for text labels.

Now, you must associate the model classes with the metadata classes.

In the **Models** folder, add a class named *PartialClasses.cs*.

Replace the contents of the file with the following code.

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoSite.Models
{
    [MetadataType(typeof(StudentMetadata))]
    public partial class Student
    {
    }

    [MetadataType(typeof(EnrollmentMetadata))]
    public partial class Enrollment
    {
    }
}
```

Notice that each class is marked as a `partial` class, and each matches the name and namespace as the class that is automatically generated. By applying the metadata attribute to the partial class, you ensure that the data validation attributes will be applied to the automatically-generated class. These attributes will not be lost when you regenerate the model classes because the metadata attribute is applied in partial classes that are not regenerated.

To regenerate the automatically-generated classes, open the *ContosoModel.edmx* file. Once again, right-click on the design surface and select **Update Model from Database**. Even though you have not changed the database,

this process will regenerate the classes. In the **Refresh** tab, select **Tables** and **Finish**.

Save the *ContosoModel.edmx* file to apply the changes.

Open the *Student.cs* file or the *Enrollment.cs* file, and notice that the data validation attributes you applied earlier are no longer in the file. However, run the application, and notice that the validation rules are still applied when you enter data.

Conclusion

This series provided a simple example of how to generate code from an existing database that enables users to edit, update, create and delete data. It used ASP.NET MVC 5, Entity Framework and ASP.NET Scaffolding to create the project.

For an introductory example of Code First development, see Getting Started with ASP.NET MVC 5.

For a more advanced example, see Creating an Entity Framework Data Model for an ASP.NET MVC 4 App. Note that the DbContext API that you use for working with data in Database First is the same as the API you use for working with data in Code First. Even if you intend to use Database First, you can learn how to handle more complex scenarios such as reading and updating related data, handling concurrency conflicts, and so forth from a Code First tutorial. The only difference is in how the database, context class, and entity classes are created.

Additional resources

For a full list of data validation annotations you can apply to properties and classes, see System.ComponentModel.DataAnnotations.

Next steps

In this tutorial, you:

- Added data annotations
- Added metadata classes

To learn how to deploy a web app and SQL database to Azure App Service, see this tutorial:

Deploy a .NET app to Azure App Service

Lifecycle of an ASP.NET MVC 5 Application

2/20/2020 • 2 minutes to read • Edit Online

by Cephas Lin

Download PDF Document

Here you can download a PDF document that charts the lifecycle of every ASP.NET MVC 5 application, from receiving the HTTP request to sending the HTTP response back to the client. It is designed both as an educational tool for those who are new to ASP.NET MVC and also as a reference for those who need to drill into specific aspects of the application. The PDF document has the following features:

- Relevant HttpApplication stages to help you understand where MVC integrates into the ASP.NET application lifecycle.
- A high-level view of the MVC application lifecycle, where you can understand the major stages that every MVC application passes through in the request processing pipeline.

- A detail view that shows drills down into the details of the request processing pipeline. You can compare the high-level view and the detail view to see how the lifecycles details are collected into the various stages.

Download PDF to see a larger view.

- Placement and purpose of all overridable methods on the Controller object in the request processing pipeline. You may or may not have the need to override any one method, but it is important for you to understand their role in the application lifecycle so that you can write code at the appropriate life cycle stage for the effect you intend.
- Blown-up diagrams showing how each of the filter types (authentication, authorization, action, and result) is invoked.
- Link to a useful article or blog from each point of interest in the detail view.

Next Steps

Does this document meet your need? We'd appreciate your feedback. If you have any question on the ASP.NET MVC lifecycle in your application, Stackoverflow and the ASP.NET MVC forums are great places to ask. Follow me on twitter so you can get updates on my latest tutorials.

- Account Confirmation and Password Recovery with ASP.NET Identity Provides details on Identity not found in Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset such as how to let users reset their forgotten password.

Azure

- Create an ASP.NET web app in Azure Short and simple tutorial for deployment to Azure.
- Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure

Performance and Debugging

- Profile and debug your ASP.NET MVC app with Glimpse

ASP.NET MVC DropDownListFor with SelectListItem

When using the DropDownListFor helper and passing to it the collection of `SelectListItem` from which it is populated, the `DropdownListFor` modifies the passed collection after it is called. `DropdownListFor` changes the `SelectListItems` Selected properties to whatever was selected by the dropdown list. This leads to unexpected

behavior.

The DropDownListFor, DropDownList, EnumDropDownListFor, ListBox, and ListBoxFor update the Selected property of any `IEnumerable<SelectListItem>` passed or found in ViewData.

The workaround is to create separate enumerables, containing distinct `SelectListItem` instances, for each property in the model.

For more information, see

- DropdownListFor modifies the SelectListItem collection passed to it
- GetSelectListWithDefaultValue Modifies IEnumerable selectList

ASP.NET MVC UI, Layouts, and Themes

Using Page Inspector in ASP.NET MVC

9/16/2020 • 9 minutes to read • Edit Online

by Tim Ammann

Page Inspector in Visual Studio 2012 is a web development tool with an integrated browser. Select any element in the integrated browser, and Page Inspector instantly highlights the element's source and CSS. You can browse any MVC view, quickly find the sources of rendered markup, and use browser tools right within the Visual Studio environment.

Watch the Video

This tutorial shows how to enable Inspection Mode, and then quickly locate and edit markup and CSS within your web project. The tutorial uses an MVC Project, but you can also use Page Inspector for Web Forms and other ASP.NET applications.

The tutorial has the following sections:

- Prerequisites
- Create a Web Application
- Use Page Inspector to Browse to a View
- Enable Inspection Mode
- Use Page Inspector to Make Changes to Markup
- Inspection Mode and the HTML Window
- Preview CSS Changes in the Styles window
- CSS Auto Sync
- Using the CSS Color Picker
- Mapping Dynamic Page Elements to JavaScript

Prerequisites

- Visual Studio 2012 or Visual Studio Express 2012 for Web.

> **NOTE**
>
> To get the latest version of Page Inspector, use Web Platform Installer to install the Windows Azure SDK for .NET 2.0.

Page Inspector is bundled with Microsoft Web Developer Tools. The latest version is 1.3. To check which version you have, run Visual Studio and select **About Microsoft Visual Studio** from the **Help** menu.

Create a Web Application

First, create a web application that you will use Page Inspector with. In Visual Studio, choose **File** > **New Project**. On the left, expand **Visual C#**, select **Web**, and then select **ASP.NET MVC4 Web Application**.

Click **OK**.

In the **New ASP.NET MVC 4 Project** dialog box, select **Internet Application**. Leave **Razor** as the default view engine.

The application opens in **Source** view.

Now that you have an application to work with, you can use Page Inspector to examine and modify it.

Use Page Inspector to Browse to a View

In Visual Studio 2012, you can right-click any view in your project, select **View in Page Inspector**, and Page Inspector will figure out the route and display the page.

In **Solution Explorer**, expand the **Views** folder and then the **Home** folder. Right click the Index.cshtml file and choose **View in Page Inspector**.

By default, Page Inspector is docked as a window on the left side of the Visual Studio environment. If you prefer, you can dock it elsewhere, or undock the window. See How to: Arrange and Dock Windows.

The top pane of the Page Inspector window shows the current page in a browser window. The bottom pane shows the page in HTML markup, along with some tabs that let you inspect different aspects of the page. The bottom pane is similar to the F12 Developer Tools in Internet Explorer.

In this tutorial, you will use the **HTML** and **Styles** tabs to navigate quickly and make changes to the application.

EnableInspection Mode

To put Page Inspector into Inspection Mode, click the **Inspect** button. In Inspection Mode, when you hold the mouse pointer over any part of the rendered page, the corresponding source markup or code is highlighted.

Now move your mouse over different parts of the page within Page Inspector. As you do, the mouse pointer changes to a large plus sign, and the element underneath is highlighted:

As you move the mouse pointer, Visual Studio highlights the corresponding Razor syntax in the source file. If the HTML element comes from another source file, Visual Studio automatically opens the file.

In Page Inspector, the **HTML** tab shows the HTML that was generated from the Razor syntax. As you move the mouse pointer, the HTML elements are highlighted. The **Styles** tab shows the CSS rules for the element.

Use Page Inspector to Make Changes to Markup

Page Inspector lets you find markup whose location might not be obvious. Then you can modify the markup and see the resulting changes.

To see this, click **Inspect** and then scroll to the bottom of the page in the Page Inspector window.

When you move the mouse pointer into the footer area, Page Inspector opens the _Layout.cshtml file and highlights the section of the layout page that you have selected. As you can see, the footer area is defined in the layout file, and not the view itself.

Now move your mouse pointer over the line with the copyright notice. In the _Layout.cshtml page, the corresponding line is highlighted.

```
<p>&copy; @DateTime.Now.Year - My ASP.NET MVC Application</p>
```

Add some text to the end of the line in the _Layout.cshtml file.

© @DateTime.Now.Year - My ASP.NET MVC Application Rocks!

Now, press Ctrl+Alt+Enter or click the Update Bar to see the results in the Page Inspector browser window.

© 2012 - My ASP.NET MVC Application Rocks!

You might have thought that the footer defined in Index.cshtml, but it turned out to be in the _Layout.cshtml, and Page Inspector found it for you.

Inspection Mode and the HTML Window

Next, you will have a quick look at the HTML window and how it maps elements for you.

Click **Inspect** to put Page Inspector in Inspection Mode.

Click the top part of the page that says "Your logo here". You are examining a particular element in more detail, so the display in the browser window no longer changes as you move the mouse pointer.

Now move the mouse pointer to the **HTML** window. As you move the mouse pointer, Page Inspector outlines the element within the **HTML** window and highlights the corresponding element in the browser window.

As before, Page Inspector opens the _Layout.cshtml file for you in a temporary tab. Click the _Layout.cshtml temporary tab, and the corresponding markup will be highlighted in the <header> section for you:

Preview CSS Changes in the Styles Window

Next, you will use the Page Inspector **Styles** window to preview changes to CSS.

Click **Inspect** to put Page Inspector in Inspection Mode.

In the Page Inspector browser window, move the mouse pointer over the "Home Page" section until the **div.content-wrapper** label appears.

Click within the div.content-wrapper section once, and then move the mouse pointer to the **Styles** window. The **Styles** window shows all of the CSS rules for this element. Scroll down to find the .featured .content-wrapper class selector. Now clear the checkbox for the background-color property.

Notice how the change previews instantly in the Page Inspector browser window.

Select the checkbox again, then double-click the property value and change it to red. The change shows immediately:

The **Styles** window makes it easy to test and preview CSS changes before you commit the changes to the style sheet itself.

CSS Auto Sync

> **NOTE**
>
> This feature requires version 1.3 of Page Inspector.

The CSS Auto-Sync feature allows you to edit a CSS file directly, and see the changes immediately in the Page Inspector browser.

Click **Inspect** to put Page Inspector in Inspection Mode.

In the Page Inspector browser, move the mouse pointer over the "Home Page" section until the **div.content-wrapper** label appears. Click once to select this element.

The **Styles** window shows all of the CSS rules for this element. Scroll down to find the .featured .content-wrapper class selector. Click on ".featured .content-wrapper". Page Inspector opens the CSS file that defines this style (Site.css) and highlights the corresponding CSS style.

Now change the value for `background-color` to "red". The change appears immediately in the Page Inspector browser.

Using the CSS Color Picker

The CSS editor in Visual Studio 2012 has a color picker that makes it easy to choose and insert colors. The color picker includes a standard palette of colors, supports standard color names, hash codes, RGB, RGBA, HSL, and HSLA colors, and maintains a list of the colors you've used most recently in the document.

In the previous section, you changed the value of the `background-color` property. To invoke the color picker, place the insertion point after the property name and type **#** or **rgb(**.

Click on a color to select it, or press the down arrow key and then use the left and right arrow keys to traverse the colors. When you visit a color, the corresponding hex value is previewed:

If the color bar doesn't have the exact color you want, you can use the color picker pop-down. To open it, click the double chevron at the right end of the color bar, or press the Down Arrow once or twice on the keyboard.

Click a color from the vertical bar on the right. This shows a gradient for that color in the main window. Choose a color directly from the vertical bar by pressing Enter, or click any point in the main window to choose with greater precision.

If there is a color on your computer screen that you want to use (it doesn't have to be inside the Visual Studio user interface), you can capture its value by using the eyedropper tool on the lower right.

You also can change the opacity of a color by moving the slider at the bottom of the color picker. Doing so changes color values to RGBA values, because the RGBA format can represent opacity.

After you have chosen a color, press Enter, and then type a semicolon to complete the background-color entry in the *Site.css* file.

The Page Inspector Update Bar

Page Inspector immediately detects the change to the *Site.css* file and displays an alert in an update bar.

To save all your files and refresh the Page Inspector browser, press Ctrl+Alt+Enter or click the update bar. The change in the highlight color appears in the browser.

Mapping Dynamic Page Elements to JavaScript

In modern web applications, elements in the page are often generated dynamically with JavaScript. That means there is no static markup (either HTML or Razor) that corresponds to these page elements.

With version 1.3, Page Inspector can now map items that were dynamically added to the page back to the corresponding JavaScript code. To demonstrate this feature, we'll use the Single Page Application (SPA) template.

> **NOTE**
>
> The SPA template requires the ASP.NET and Web Tools 2012.2 update.

In Visual Studio, choose **File** > **New Project**. On the left, expand **Visual C#**, select **Web**, and then select **ASP.NET MVC4 Web Application**. Click **OK**.

In the **New ASP.NET MVC 4 Project** dialog, select **Single Page Application**.

In Solution Explorer, expand the **Views** folder and then the **Home** folder. Right click the Index.cshtml file and choose **View in Page Inspector**.

The first thing that is displayed in the Page Inspector browser is a login page. Click "Sign Up" and create a user

name and password. Once you sign up, the application logs you in and creates a to-do list with some sample items.

Click **Inspect** to put Page Inspector in Inspection Mode. In the Page Inspector browser, click on one of the to-do items. Notice that instead of being highlighted in blue, the element is highlighted in orange, with "JS" next to the element name. This indicates that the element was created dynamically through script.

In addition, an orange underline appears on the **Call Stack** tab. This indicates that the **Call Stack** pane has more information about the element.

Click on the **Call Stack** tab. The **Call Stack** pane shows the call stack for the JavaScript call that created the element. Calls to external libraries such as jQuery are collapsed, so that you can easily see the calls to your application script.

To see the full stack, including calls to external libraries, you can expand the nodes labeled "External Libraries":

If you click an item in the call stack, Visual Studio opens the code file and highlights the corresponding script.

```
function getTodoLists(todoListsObservable, errorObservable) {
    return ajaxRequest("get", todoListUrl())
        .done(getSucceeded)
        .fail(getFailed);

    function getSucceeded(data) {
        var mappedTodoLists = $.map(data, function (list) { returr
        todoListsObservable(mappedTodoLists);
    }
```

Dynamic v. Strongly Typed Views

9/16/2020 • 2 minutes to read • Edit Online

by Rick Anderson

There are three ways to pass information from a controller to a view in ASP.NET MVC 3:

1. As a strongly typed model object.
2. As a dynamic type (using @model dynamic)
3. Using the ViewBag

I've written a simple MVC 3 Top Blog application to compare and contrast dynamic and strongly typed views. The controller starts out with a simple list of blogs:

```
using System.Collections.Generic;
using System.Web.Mvc;

namespace Mvc3ViewDemo.Controllers {

    public class Blog {
        public string Name;
        public string URL;
    }

    public class HomeController : Controller {

        List<Blog> topBlogs = new List<Blog>
      {
          new Blog { Name = "ScottGu", URL = "http://weblogs.asp.net/scottgu/"},
          new Blog { Name = "Scott Hanselman", URL = "http://www.hanselman.com/blog/"},
          new Blog { Name = "Jon Galloway", URL = "http://www.asp.net/mvc"}
      };

        public ActionResult IndexNotStonglyTyped() {
            return View(topBlogs);
        }

        public ActionResult About() {
            ViewBag.Message = "Welcome to ASP.NET MVC!";
            return View();
        }
    }
}
```

Right click in the IndexNotStonglyTyped() method and add a Razor view.

Make sure the **Create a strongly-typed view** box is not checked. The resulting view doesn't contain much:

```
@{
    ViewBag.Title = "IndexNotStonglyTyped";
}

<h2>IndexNotStonglyTyped</h2>

On the first line of the Views\Home\IndexNotStonglyTyped.cshtml file, add the model directive and the dynamic
keyword.
```

```
@model dynamic
```

Because we're using a dynamic and not a strongly typed view, intellisense doesn't help us. The completed code is shown below:

```
@model dynamic

@{
    ViewBag.Title = "IndexNotStonglyTyped";
}

<h2>Index Not Stongly Typed</h2>

<p>
 <ul>
@foreach (var blog in Model) {
   <li>
    <a href="@blog.URL">@blog.Name</a>
   </li>
}
 </ul>
</p>
```

Now we'll add a strongly typed view. Add the following code to the controller:

```
public ActionResult StonglyTypedIndex() {
    return View(topBlogs);
}
```

Notice it's exactly the same return View(topBlogs); call as the non-strongly typed view. Right click inside of *StonglyTypedIndex()* and select **Add View**. This time select the **Blog** Model class and select **List** as the Scaffold template.

Inside the new view template we get intellisense support.

```
@model IEnumerable<Mvc3ViewDemo.Controllers.Blog>
@{
    ViewBag.Title = "StonglyTypedIndex";
}
<h2> Stongly Typed Index</h2>

<ul>
@foreach (var item in Model) {

    <li><a href="@item.URL">@item.</a> </li>
}
</ul>
```

Security, Authentication, and Authorization with ASP.NET MVC

2/20/2020 • 2 minutes to read • Edit Online

How to make an ASP.NET site more secure, and how to implement authentication and authorization.

- Create an ASP.NET MVC 5 App with Facebook, Twitter, LinkedIn and Google OAuth2 Sign-on (C#)
- Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset (C#)
- ASP.NET MVC 5 app with SMS and email Two-Factor Authentication
- XSRF/CSRF Prevention in ASP.NET MVC and Web Pages
- Preventing Open Redirection Attacks (C#)

Create an ASP.NET MVC 5 App with Facebook, Twitter, LinkedIn and Google OAuth2 Sign-on (C#)

2/20/2020 • 11 minutes to read • Edit Online

by Rick Anderson

This tutorial shows you how to build an ASP.NET MVC 5 web application that enables users to log in using OAuth 2.0 with credentials from an external authentication provider, such as Facebook, Twitter, LinkedIn, Microsoft, or Google. For simplicity, this tutorial focuses on working with credentials from Facebook and Google.

Enabling these credentials in your web sites provides a significant advantage because millions of users already have accounts with these external providers. These users may be more inclined to sign up for your site if they do not have to create and remember a new set of credentials.

See also ASP.NET MVC 5 app with SMS and email Two-Factor Authentication.

The tutorial also shows how to add profile data for the user, and how to use the Membership API to add roles. This tutorial was written by Rick Anderson (Please follow me on Twitter: @RickAndMSFT).

Getting Started

Start by installing and running Visual Studio Express 2013 for Web or Visual Studio 2013. Install Visual Studio 2013 Update 3 or higher. For help with Dropbox, GitHub, Linkedin, Instagram, Buffer, Salesforce, STEAM, Stack Exchange, Tripit, Twitch, Twitter, Yahoo!, and more, see this sample project.

> **NOTE**
>
> You must install Visual Studio 2013 Update 3 or higher to use Google OAuth 2 and to debug locally without SSL warnings.

Click **New Project** from the **Start** page, or you can use the menu and select **File**, and then **New Project**.

Creating Your First Application

Click **New Project**, then select **Visual C#** on the left, then **Web** and then select **ASP.NET Web Application**. Name your project "MvcAuth" and then click **OK**.

In the **New ASP.NET Project** dialog, click **MVC**. If the Authentication is not **Individual User Accounts**, click the **Change Authentication** button and select **Individual User Accounts**. By checking **Host in the cloud**, the app will be very easy to host in Azure.

If you selected **Host in the cloud**, complete the configure dialog.

Use NuGet to update to the latest OWIN middleware

Use the NuGet package manager to update the OWIN middleware. Select **Updates** in the left menu. You can click on the **Update All** button or you can search for only OWIN packages (shown in the next image):

In the image below, only OWIN packages are shown:

From the Package Manager Console (PMC), you can enter the `Update-Package` command, which will update all packages.

Press **F5** or **Ctrl+F5** to run the application. In the image below, the port number is 1234. When you run the application, you'll see a different port number.

Depending on the size of your browser window, you might need to click the navigation icon to see the **Home**, **About**, **Contact**, **Register** and **Log in** links.

Setting up SSL in the Project

To connect to authentication providers like Google and Facebook, you will need to set up IIS-Express to use SSL. It's important to keep using SSL after login and not drop back to HTTP, your login cookie is just as secret as your username and password, and without using SSL you're sending it in clear-text across the wire. Besides, you've already taken the time to perform the handshake and secure the channel (which is the bulk of what makes HTTPS slower than HTTP) before the MVC pipeline is run, so redirecting back to HTTP after you're logged in won't make the current request or future requests much faster.

1. In **Solution Explorer**, click the **MvcAuth** project.
2. Hit the F4 key to show the project properties. Alternatively, from the **View** menu you can select **Properties Window**.
3. Change **SSL Enabled** to True.

4. Copy the SSL URL (which will be `https://localhost:44300/` unless you've created other SSL projects).
5. In **Solution Explorer**, right click the **MvcAuth** project and select **Properties**.

6. Select the **Web** tab, and then paste the SSL URL into the **Project Url** box. Save the file (Ctl+S). You will need this URL to configure Facebook and Google authentication apps.

7. Add the RequireHttps attribute to the `Home` controller to require all requests must use HTTPS. A more secure approach is to add the RequireHttps filter to the application. See the section "Protect the Application with SSL and the Authorize Attribute" in my tutorial Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure App Service. A portion of the Home controller is shown below.

```
[RequireHttps]
public class HomeController : Controller
{
   public ActionResult Index()
   {
      return View();
   }
```

8. Press CTRL+F5 to run the application. If you've installed the certificate in the past, you can skip the rest of this section and jump to Creating a Google app for OAuth 2 and connecting the app to the project, otherwise, follow the instructions to trust the self-signed certificate that IIS Express has generated.

9. Read the **Security Warning** dialog and then click **Yes** if you want to install the certificate representing localhost.

10. IE shows the *Home* page and there are no SSL warnings.

11. Google Chrome also accepts the certificate and will show HTTPS content without a warning. Firefox uses its own certificate store, so it will display a warning. For our application you can safely click **I Understand the Risks**.

Creating a Google app for OAuth 2 and connecting the app to the project

> **WARNING**
>
> For current Google OAuth instructions, see Configuring Google authentication in ASP.NET Core.

1. Navigate to the Google Developers Console.
2. If you haven't created a project before, select **Credentials** in the left tab, and then select **Create**.
3. In the left tab, click **Credentials**.
4. Click **Create credentials** then **OAuth client ID**.
   a. In the **Create Client ID** dialog, keep the default **Web application** for the application type.
   b. Set the **Authorized JavaScript** origins to the SSL URL you used above (`https://localhost:44300/` unless you've created other SSL projects)
   c. Set the **Authorized redirect URI** to: `https://localhost:44300/signin-google`
5. Click the OAuth Consent screen menu item, then set your email address and product name. When you have completed the form click **Save**.
6. Click the Library menu item, search **Google+ API**, click on it then press Enable.

Google Spectrum Database API	1,000 requests/day	OFF
Google Webmaster Tools API	1,000,000 requests/day	OFF
Google+ API	10,000 requests/day	OFF
Google+ Domains API	10,000 requests/day	OFF
Google+ Hangouts API		OFF
Groups Migration API	500,000 requests/day	OFF
Groups Settings API	100,000 requests/day	OFF
Identity Toolkit API	1,000,000 requests/day	OFF

The image below shows the enabled APIs.

7. From the Google APIs API Manager, visit the **Credentials** tab to obtain the **Client ID**. Download to save a JSON file with application secrets. Copy and paste the **ClientId** and **ClientSecret** into the `UseGoogleAuthentication` method found in the *Startup.Auth.cs* file in the *App_Start* folder. The **ClientId** and **ClientSecret** values shown below are samples and don't work.

```
public void ConfigureAuth(IAppBuilder app)
{
    // Configure the db context and user manager to use a single instance per request
    app.CreatePerOwinContext(ApplicationDbContext.Create);
    app.CreatePerOwinContext<ApplicationUserManager>(ApplicationUserManager.Create);

    // Enable the application to use a cookie to store information for the signed in user
    // and to use a cookie to temporarily store information about a user logging in with a third
party login provider
    // Configure the sign in cookie
    app.UseCookieAuthentication(new CookieAuthenticationOptions
    {
        AuthenticationType = DefaultAuthenticationTypes.ApplicationCookie,
        LoginPath = new PathString("/Account/Login"),
        Provider = new CookieAuthenticationProvider
        {
            OnValidateIdentity = SecurityStampValidator.OnValidateIdentity<ApplicationUserManager,
ApplicationUser>(
                validateInterval: TimeSpan.FromMinutes(30),
                regenerateIdentity: (manager, user) => user.GenerateUserIdentityAsync(manager))
        }
    });

    app.UseExternalSignInCookie(DefaultAuthenticationTypes.ExternalCookie);

    // Uncomment the following lines to enable logging in with third party login providers
    //app.UseMicrosoftAccountAuthentication(
    //    clientId: "",
    //    clientSecret: "");

    //app.UseTwitterAuthentication(
    //   consumerKey: "",
    //   consumerSecret: "");

    //app.UseFacebookAuthentication(
    //   appId: "",
    //   appSecret: "");

    app.UseGoogleAuthentication(
         clientId: "000-000.apps.googleusercontent.com",
         clientSecret: "00000000000");
}
```

WARNING

Security - Never store sensitive data in your source code. The account and credentials are added to the code above to keep the sample simple. See Best practices for deploying passwords and other sensitive data to ASP.NET and Azure App Service.

8. Press **CTRL+F5** to build and run the application. Click the **Log in** link.

9. Under **Use another service to log in**, click **Google**.

> **NOTE**
>
> If you miss any of the steps above you will get a HTTP 401 error. Recheck your steps above. If you miss a required setting (for example **product name**), add the missing item and save; it can take a few minutes for authentication to work.

10. You will be redirected to the Google site where you will enter your credentials.

11. After you enter your credentials, you will be prompted to give permissions to the web application you just created:

12. Click **Accept**. You will now be redirected back to the **Register** page of the MvcAuth application where you can register your Google account. You have the option of changing the local email registration name used for your Gmail account, but you generally want to keep the default email alias (that is, the one you used for authentication). Click **Register**.

Creating the app in Facebook and connecting the app to the project

> **WARNING**
>
> For current Facebook OAuth2 authentication instructions, see Configuring Facebook authentication

Examine the Membership Data

In the **View** menu, click **Server Explorer**.

Expand **DefaultConnection (MvcAuth)**, expand **Tables**, right click **AspNetUsers** and click **Show Table Data**.

dbo.AspNetUsers [Data]

Max Rows: 1000

Id	Email	EmailConfirmed	PasswordHash	SecurityStamp	PhoneNumber
3878-475f87d6efa0	rick.FB@contoso.com	False	NULL	4fb9fed9-0028-...	NULL
727d3bc0-74cf-...	rickandmsft@gmail.com	False	NULL	228178d3-d11f-...	NULL
NULL	NULL	NULL	NULL	NULL	NULL

Adding Profile Data to the User Class

In this section you'll add birth date and home town to the user data during registration, as shown in the following image.

Open the *Models\IdentityModels.cs* file and add birth date and home town properties:

```
public class ApplicationUser : IdentityUser
{
    public string HomeTown { get; set; }
    public System.DateTime? BirthDate { get; set; }
    public async Task<ClaimsIdentity> GenerateUserIdentityAsync(UserManager<ApplicationUser> manager)
    {
        // Note the authenticationType must match the one defined in
CookieAuthenticationOptions.AuthenticationType
        var userIdentity = await manager.CreateIdentityAsync(this,
DefaultAuthenticationTypes.ApplicationCookie);
        // Add custom user claims here
        return userIdentity;
    }
}
```

Open the *Models\AccountViewModels.cs* file and the set birth date and home town properties in `ExternalLoginConfirmationViewModel`.

```
public class ExternalLoginConfirmationViewModel
{
    [Required]
    [EmailAddress]
    [Display(Name = "Email")]
    public string Email { get; set; }

    public string HomeTown { get; set; }
    public System.DateTime? BirthDate { get; set; }
}
```

Open the *Controllers\AccountController.cs* file and add code for birth date and home town in the `ExternalLoginConfirmation` action method as shown:

```
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> ExternalLoginConfirmation(ExternalLoginConfirmationViewModel model, string
returnUrl)
{
    if (User.Identity.IsAuthenticated)
    {
        return RedirectToAction("Manage");
    }

    if (ModelState.IsValid)
    {
        // Get the information about the user from the external login provider
        var info = await AuthenticationManager.GetExternalLoginInfoAsync();
        if (info == null)
        {
            return View("ExternalLoginFailure");
        }
        var user = new ApplicationUser()
        {
            UserName = model.Email, Email = model.Email,
            BirthDate = model.BirthDate,
            HomeTown  = model.HomeTown

        };
        IdentityResult result = await UserManager.CreateAsync(user);
        if (result.Succeeded)
        {
            result = await UserManager.AddLoginAsync(user.Id, info.Login);
            if (result.Succeeded)
            {
                await SignInAsync(user, isPersistent: false);

                // For more information on how to enable account confirmation and password reset please
visit https://go.microsoft.com/fwlink/?LinkID=320771
                // Send an email with this link
                // string code = await UserManager.GenerateEmailConfirmationTokenAsync(user.Id);
                // var callbackUrl = Url.Action("ConfirmEmail", "Account", new { userId = user.Id, code =
code }, protocol: Request.Url.Scheme);
                // SendEmail(user.Email, callbackUrl, "Confirm your account", "Please confirm your account
by clicking this link");

                return RedirectToLocal(returnUrl);
            }
        }
        AddErrors(result);
    }

    ViewBag.ReturnUrl = returnUrl;
    return View(model);
}
```

Add birth date and home town to the *Views\Account\ExternalLoginConfirmation.cshtml* file:

```
@model MvcAuth.Models.ExternalLoginConfirmationViewModel
@{
    ViewBag.Title = "Register";
}
<h2>@ViewBag.Title.</h2>
<h3>Associate your @ViewBag.LoginProvider account.</h3>

@using (Html.BeginForm("ExternalLoginConfirmation", "Account", new { ReturnUrl = ViewBag.ReturnUrl },
FormMethod.Post, new { @class = "form-horizontal", role = "form" }))
{
    @Html.AntiForgeryToken()

    <h4>Association Form</h4>
    <hr />
    @Html.ValidationSummary(true, "", new { @class = "text-danger" })
    <p class="text-info">
        You've successfully authenticated with <strong>@ViewBag.LoginProvider</strong>.
            Please enter a user name for this site below and click the Register button to finish
            logging in.
    </p>
    <div class="form-group">
        @Html.LabelFor(m => m.Email, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.TextBoxFor(m => m.Email, new { @class = "form-control" })
            @Html.ValidationMessageFor(m => m.Email, "", new { @class = "text-danger" })
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.HomeTown, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.TextBoxFor(m => m.HomeTown, new { @class = "form-control" })
            @Html.ValidationMessageFor(m => m.HomeTown)
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.BirthDate, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.TextBoxFor(m => m.BirthDate, new { @class = "form-control" })
            @Html.ValidationMessageFor(m => m.BirthDate)
        </div>
    </div>
    <div class="form-group">
        <div class="col-md-offset-2 col-md-10">
            <input type="submit" class="btn btn-default" value="Register" />
        </div>
    </div>
}

@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

Delete the membership database so you can again register your Facebook account with your application and verify you can add the new birth date and home town profile information.

From **Solution Explorer**, click the **Show All Files** icon, then right click *Add_Data\aspnet-MvcAuth-<dateStamp>.mdf* and click **Delete**.

From the **Tools** menu, click **NuGet Package Manger**, then click **Package Manager Console** (PMC). Enter the following commands in the PMC.

1. Enable-Migrations
2. Add-Migration Init
3. Update-Database

Run the application and use FaceBook and Google to log in and register some users.

Examine the Membership Data

In the **View** menu, click **Server Explorer**.

Right click **AspNetUsers** and click **Show Table Data**.

The `HomeTown` and `BirthDate` fields are shown below.

dbo.AspNetUsers [Data]

Max Rows: 1000

Id	HomeTown	BirthDate	Email	EmailConfirmed
eaa1081f	Captown	7/7/1977 12:00:...	Scott@contoso.com	False
a64159...	Redmond	1/2/1903 12:00:...	Rick2@Contoso.com	False
b2d94...	Great Falls	8/8/1988 12:00:...	RickAndMSFT@gm...	False
NULL	NULL	NULL	NULL	NULL

Logging off your App and Logging in With Another Account

If you log on to your app with Facebook,, and then log out and try to log in again with a different Facebook account (using the same browser), you will be immediately logged in to the previous Facebook account you used. In order to use another account, you need to navigate to Facebook and log out at Facebook. The same rule applies to any other 3rd party authentication provider. Alternatively, you can log in with another account by using a different browser.

Next Steps

See Introducing the Yahoo and LinkedIn OAuth security providers for OWIN by Jerrie Pelser for Yahoo and LinkedIn instructions. See Jerrie's Pretty social login buttons for ASP.NET MVC 5 to get enable social login buttons.

Follow my tutorial Create an ASP.NET MVC app with auth and SQL DB and deploy to Azure App Service, which continues this tutorial and shows the following:

1. How to deploy your app to Azure.
2. How to secure you app with roles.
3. How to secure your app with the RequireHttps and Authorize filters.
4. How to use the membership API to add users and roles.

Please leave feedback on how you liked this tutorial and what we could improve. You can also request new topics at Show Me How With Code. You can even ask for and vote on new features to be added to ASP.NET. For example, you can vote for a tool to create and manage users and roles.

For an good explanation of how ASP.NET External Authentication Services work, see Robert McMurray's External Authentication Services. Robert's article also goes into detail in enabling Microsoft and Twitter authentication. Tom Dykstra's excellent EF/MVC tutorial shows how to work with the Entity Framework.

Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset (C#)

2/20/2020 • 12 minutes to read • Edit Online

by Rick Anderson

This tutorial shows you how to build an ASP.NET MVC 5 web app with email confirmation and password reset using the ASP.NET Identity membership system.

For an updated version of this tutorial that uses .NET Core, see Account confirmation and password recovery in ASP.NET Core.

Create an ASP.NET MVC app

Start by installing and running Visual Studio Express 2013 for Web or Visual Studio 2013. Install Visual Studio 2013 Update 3 or higher.

> **NOTE**
>
> Warning: You must install Visual Studio 2013 Update 3 or higher to complete this tutorial.

1. Create a new ASP.NET Web project and select the MVC template. Web Forms also supports ASP.NET Identity, so you could follow similar steps in a web forms app.

2. Leave the default authentication as **Individual User Accounts**. If you'd like to host the app in Azure, leave the check box checked. Later in the tutorial we will deploy to Azure. You can open an Azure account for free.

3. Set the project to use SSL.

4. Run the app, click the **Register** link and register a user. At this point, the only validation on the email is with the [EmailAddress] attribute.

5. In Server Explorer, navigate to **Data Connections\DefaultConnection\Tables\AspNetUsers**, right click and select **Open table definition**.

   The following image shows the `AspNetUsers` schema:

6. Right click on the **AspNetUsers** table and select **Show Table Data**.

   At this point the email has not been confirmed.

7. Click on the row and select delete. You'll add this email again in the next step, and send a confirmation email.

Email confirmation

It's a best practice to confirm the email of a new user registration to verify they are not impersonating someone else (that is, they haven't registered with someone else's email). Suppose you had a discussion forum, you would want to prevent `"bob@example.com"` from registering as `"joe@contoso.com"`. Without email confirmation, `"joe@contoso.com"` could get unwanted email from your app. Suppose Bob accidentally registered as `"bib@example.com"` and hadn't noticed it, he wouldn't be able to use password recover because the app doesn't have his correct email. Email confirmation provides only limited protection from bots and doesn't provide protection from determined spammers, they have many working email aliases they can use to register.

You generally want to prevent new users from posting any data to your web site before they have been confirmed by email, a SMS text message or another mechanism. In the sections below, we will enable email confirmation and modify the code to prevent newly registered users from logging in until their email has been confirmed.

Hook up SendGrid

The instructions in this section are not current. See Configure SendGrid email provider for updated instructions.

Although this tutorial only shows how to add email notification through SendGrid, you can send email using SMTP and other mechanisms (see additional resources).

1. In the Package Manager Console, enter the following command:

```
Install-Package SendGrid
```

2. Go to the Azure SendGrid sign up page and register for a free SendGrid account. Configure SendGrid by adding code similar to the following in *App_Start/IdentityConfig.cs*:

```
public class EmailService : IIdentityMessageService
{
   public async Task SendAsync(IdentityMessage message)
   {
      await configSendGridasync(message);
   }

   // Use NuGet to install SendGrid (Basic C# client lib)
   private async Task configSendGridasync(IdentityMessage message)
   {
      var myMessage = new SendGridMessage();
      myMessage.AddTo(message.Destination);
      myMessage.From = new System.Net.Mail.MailAddress(
                          "Joe@contoso.com", "Joe S.");
      myMessage.Subject = message.Subject;
      myMessage.Text = message.Body;
      myMessage.Html = message.Body;

      var credentials = new NetworkCredential(
                 ConfigurationManager.AppSettings["mailAccount"],
                 ConfigurationManager.AppSettings["mailPassword"]
                 );

      // Create a Web transport for sending email.
      var transportWeb = new Web(credentials);

      // Send the email.
      if (transportWeb != null)
      {
         await transportWeb.DeliverAsync(myMessage);
      }
      else
      {
         Trace.TraceError("Failed to create Web transport.");
         await Task.FromResult(0);
      }
   }
}
```

You'll need to add the following includes:

```
using SendGrid;
using System.Net;
using System.Configuration;
using System.Diagnostics;
```

To keep this sample simple, we'll store the app settings in the *web.config* file:

```
</connectionStrings>
   <appSettings>
      <add key="webpages:Version" value="3.0.0.0" />
      <!-- Markup removed for clarity. -->

      <add key="mailAccount" value="xyz" />
      <add key="mailPassword" value="password" />
   </appSettings>
  <system.web>
```

WARNING

Security - Never store sensitive data in your source code. The account and credentials are stored in the appSetting. On Azure, you can securely store these values on the **Configure** tab in the Azure portal. See Best practices for deploying passwords and other sensitive data to ASP.NET and Azure.

Enable email confirmation in the Account controller

```
//
// POST: /Account/Register
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = new ApplicationUser { UserName = model.Email, Email = model.Email };
        var result = await UserManager.CreateAsync(user, model.Password);
        if (result.Succeeded)
        {
            await SignInManager.SignInAsync(user, isPersistent:false, rememberBrowser:false);

            string code = await UserManager.GenerateEmailConfirmationTokenAsync(user.Id);
            var callbackUrl = Url.Action("ConfirmEmail", "Account",
               new { userId = user.Id, code = code }, protocol: Request.Url.Scheme);
            await UserManager.SendEmailAsync(user.Id,
               "Confirm your account", "Please confirm your account by clicking <a href=\""
               + callbackUrl + "\">here</a>");

            return RedirectToAction("Index", "Home");
        }
        AddErrors(result);
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

Verify the *Views\Account\ConfirmEmail.cshtml* file has correct razor syntax. (The @ character in the first line might be missing.)

```
@{
    ViewBag.Title = "Confirm Email";
}

<h2>@ViewBag.Title.</h2>
<div>
    <p>
        Thank you for confirming your email. Please @Html.ActionLink("Click here to Log in", "Login",
"Account", routeValues: null, htmlAttributes: new { id = "loginLink" })
    </p>
</div>
```

Run the app and click the Register link. Once you submit the registration form, you are logged in.

Check your email account and click on the link to confirm your email.

Require email confirmation before log in

Currently once a user completes the registration form, they are logged in. You generally want to confirm their email before logging them in. In the section below, we will modify the code to require new users to have a confirmed email before they are logged in (authenticated). Update the `HttpPost Register` method with the following highlighted changes:

```
//
// POST: /Account/Register
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
   if (ModelState.IsValid)
   {
      var user = new ApplicationUser { UserName = model.Email, Email = model.Email };
      var result = await UserManager.CreateAsync(user, model.Password);
      if (result.Succeeded)
      {
         //  Comment the following line to prevent log in until the user is confirmed.
         //  await SignInManager.SignInAsync(user, isPersistent:false, rememberBrowser:false);

         string code = await UserManager.GenerateEmailConfirmationTokenAsync(user.Id);
         var callbackUrl = Url.Action("ConfirmEmail", "Account",
            new { userId = user.Id, code = code }, protocol: Request.Url.Scheme);
         await UserManager.SendEmailAsync(user.Id, "Confirm your account",
            "Please confirm your account by clicking <a href=\"" + callbackUrl + "\">here</a>");

         // Uncomment to debug locally
         // TempData["ViewBagLink"] = callbackUrl;

         ViewBag.Message = "Check your email and confirm your account, you must be confirmed "
                         + "before you can log in.";

         return View("Info");
         //return RedirectToAction("Index", "Home");
      }
      AddErrors(result);
   }

   // If we got this far, something failed, redisplay form
   return View(model);
}
```

By commenting out the `SignInAsync` method, the user will not be signed in by the registration. The `TempData["ViewBagLink"] = callbackUrl;` line can be used to debug the app and test registration without sending email. `ViewBag.Message` is used to display the confirm instructions. The download sample contains code to test email confirmation without setting up email, and can also be used to debug the application.

Create a `Views\Shared\Info.cshtml` file and add the following razor markup:

```
@{
   ViewBag.Title = "Info";
}
<h2>@ViewBag.Title.</h2>
<h3>@ViewBag.Message</h3>
```

Add the Authorize attribute to the `Contact` action method of the Home controller. You can click on the **Contact** link to verify anonymous users don't have access and authenticated users do have access.

```
[Authorize]
public ActionResult Contact()
{
   ViewBag.Message = "Your contact page.";

   return View();
}
```

You must also update the `HttpPost Login` action method:

```
//
// POST: /Account/Login
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Login(LoginViewModel model, string returnUrl)
{
    if (!ModelState.IsValid)
    {
        return View(model);
    }

    // Require the user to have a confirmed email before they can log on.
    var user = await UserManager.FindByNameAsync(model.Email);
    if (user != null)
    {
       if (!await UserManager.IsEmailConfirmedAsync(user.Id))
       {
          ViewBag.errorMessage = "You must have a confirmed email to log on.";
          return View("Error");
       }
    }

    // This doesn't count login failures towards account lockout
    // To enable password failures to trigger account lockout, change to shouldLockout: true
    var result = await SignInManager.PasswordSignInAsync(model.Email, model.Password, model.RememberMe,
shouldLockout: false);
    switch (result)
    {
        case SignInStatus.Success:
            return RedirectToLocal(returnUrl);
        case SignInStatus.LockedOut:
            return View("Lockout");
        case SignInStatus.RequiresVerification:
            return RedirectToAction("SendCode", new { ReturnUrl = returnUrl, RememberMe = model.RememberMe
});
        case SignInStatus.Failure:
        default:
            ModelState.AddModelError("", "Invalid login attempt.");
            return View(model);
    }
}
```

Update the *Views\Shared\Error.cshtml* view to display the error message:

```
@model System.Web.Mvc.HandleErrorInfo

@{
    ViewBag.Title = "Error";
}

<h1 class="text-danger">Error.</h1>
@{
   if (String.IsNullOrEmpty(ViewBag.errorMessage))
   {
      <h2 class="text-danger">An error occurred while processing your request.</h2>
   }
   else
   {
      <h2 class="text-danger">@ViewBag.errorMessage</h2>
   }
}
```

Delete any accounts in the **AspNetUsers** table that contain the email alias you wish to test with. Run the app and verify you can't log in until you have confirmed your email address. Once you confirm your email address, click the **Contact** link.

Password recovery/reset

Remove the comment characters from the `HttpPost ForgotPassword` action method in the account controller:

```
//
// POST: /Account/ForgotPassword
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> ForgotPassword(ForgotPasswordViewModel model)
{
    if (ModelState.IsValid)
    {
        var user = await UserManager.FindByNameAsync(model.Email);
        if (user == null || !(await UserManager.IsEmailConfirmedAsync(user.Id)))
        {
            // Don't reveal that the user does not exist or is not confirmed
            return View("ForgotPasswordConfirmation");
        }

        string code = await UserManager.GeneratePasswordResetTokenAsync(user.Id);
        var callbackUrl = Url.Action("ResetPassword", "Account", new { userId = user.Id, code = code },
protocol: Request.Url.Scheme);
        await UserManager.SendEmailAsync(user.Id, "Reset Password", "Please reset your password by clicking
<a href=\"" + callbackUrl + "\">here</a>");
        return RedirectToAction("ForgotPasswordConfirmation", "Account");
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

Remove the comment characters from the `ForgotPassword` ActionLink in the *Views\Account\Login.cshtml* razor view file:

```
@using MvcPWy.Models
@model LoginViewModel
@{
   ViewBag.Title = "Log in";
}

<h2>@ViewBag.Title.</h2>
<div class="row">
   <div class="col-md-8">
      <section id="loginForm">
         @using (Html.BeginForm("Login", "Account", new { ReturnUrl = ViewBag.ReturnUrl }, FormMethod.Post,
new { @class = "form-horizontal", role = "form" }))
         {
            @Html.AntiForgeryToken()
            <h4>Use a local account to log in.</h4>
            <hr />
            @Html.ValidationSummary(true, "", new { @class = "text-danger" })
            <div class="form-group">
               @Html.LabelFor(m => m.Email, new { @class = "col-md-2 control-label" })
               <div class="col-md-10">
                  @Html.TextBoxFor(m => m.Email, new { @class = "form-control" })
                  @Html.ValidationMessageFor(m => m.Email, "", new { @class = "text-danger" })
               </div>
            </div>
            <div class="form-group">
               @Html.LabelFor(m => m.Password, new { @class = "col-md-2 control-label" })
               <div class="col-md-10">
                  @Html.PasswordFor(m => m.Password, new { @class = "form-control" })
                  @Html.ValidationMessageFor(m => m.Password, "", new { @class = "text-danger" })
               </div>
            </div>
            <div class="form-group">
               <div class="col-md-offset-2 col-md-10">
                  <div class="checkbox">
                     @Html.CheckBoxFor(m => m.RememberMe)
                     @Html.LabelFor(m => m.RememberMe)
                  </div>
               </div>
            </div>
            <div class="form-group">
               <div class="col-md-offset-2 col-md-10">
                  <input type="submit" value="Log in" class="btn btn-default" />
               </div>
            </div>
            <p>
               @Html.ActionLink("Register as a new user", "Register")
            </p>
            @* Enable this once you have account confirmation enabled for password reset functionality *@
            <p>
               @Html.ActionLink("Forgot your password?", "ForgotPassword")
            </p>
         }
      </section>
   </div>
   <div class="col-md-4">
      <section id="socialLoginForm">
         @Html.Partial("_ExternalLoginsListPartial", new ExternalLoginListViewModel { ReturnUrl =
ViewBag.ReturnUrl })
      </section>
   </div>
</div>

@section Scripts {
   @Scripts.Render("~/bundles/jqueryval")
}
```

The Log in page will now show a link to reset the password.

Resend email confirmation link

Once a user creates a new local account, they are emailed a confirmation link they are required to use before they can log on. If the user accidentally deletes the confirmation email, or the email never arrives, they will need the confirmation link sent again. The following code changes show how to enable this.

Add the following helper method to the bottom of the *Controllers\AccountController.cs* file:

```
private async Task<string> SendEmailConfirmationTokenAsync(string userID, string subject)
{
   string code = await UserManager.GenerateEmailConfirmationTokenAsync(userID);
   var callbackUrl = Url.Action("ConfirmEmail", "Account",
      new { userId = userID, code = code }, protocol: Request.Url.Scheme);
   await UserManager.SendEmailAsync(userID, subject,
      "Please confirm your account by clicking <a href=\"" + callbackUrl + "\">here</a>");

   return callbackUrl;
}
```

Update the Register method to use the new helper:

```
//
// POST: /Account/Register
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Register(RegisterViewModel model)
{
   if (ModelState.IsValid)
   {
      var user = new ApplicationUser { UserName = model.Email, Email = model.Email };
      var result = await UserManager.CreateAsync(user, model.Password);
      if (result.Succeeded)
      {
         //  Comment the following line to prevent log in until the user is confirmed.
         //  await SignInManager.SignInAsync(user, isPersistent:false, rememberBrowser:false);

         string callbackUrl = await SendEmailConfirmationTokenAsync(user.Id, "Confirm your account");

         ViewBag.Message = "Check your email and confirm your account, you must be confirmed "
                         + "before you can log in.";

         return View("Info");
         //return RedirectToAction("Index", "Home");
      }
      AddErrors(result);
   }

   // If we got this far, something failed, redisplay form
   return View(model);
}
```

Update the Login method to resend the password if the user account has not been confirmed:

```
//
// POST: /Account/Login
[HttpPost]
[AllowAnonymous]
[ValidateAntiForgeryToken]
public async Task<ActionResult> Login(LoginViewModel model, string returnUrl)
{
   if (!ModelState.IsValid)
   {
      return View(model);
   }

   // Require the user to have a confirmed email before they can log on.
  // var user = await UserManager.FindByNameAsync(model.Email);
   var user =  UserManager.Find(model.Email, model.Password);
   if (user != null)
   {
      if (!await UserManager.IsEmailConfirmedAsync(user.Id))
      {
         string callbackUrl = await SendEmailConfirmationTokenAsync(user.Id, "Confirm your account-Resend");

          // Uncomment to debug locally
          // ViewBag.Link = callbackUrl;
         ViewBag.errorMessage = "You must have a confirmed email to log on. "
                              + "The confirmation token has been resent to your email account.";
         return View("Error");
      }
   }

   // This doesn't count login failures towards account lockout
   // To enable password failures to trigger account lockout, change to shouldLockout: true
   var result = await SignInManager.PasswordSignInAsync(model.Email, model.Password, model.RememberMe,
shouldLockout: false);
   switch (result)
   {
      case SignInStatus.Success:
         return RedirectToLocal(returnUrl);
      case SignInStatus.LockedOut:
         return View("Lockout");
      case SignInStatus.RequiresVerification:
         return RedirectToAction("SendCode", new { ReturnUrl = returnUrl, RememberMe = model.RememberMe });
      case SignInStatus.Failure:
      default:
         ModelState.AddModelError("", "Invalid login attempt.");
         return View(model);
   }
}
```

Combine social and local login accounts

You can combine local and social accounts by clicking on your email link. In the following sequence **RickAndMSFT@gmail.com** is first created as a local login, but you can create the account as a social log in first, then add a local login.

Click on the **Manage** link. Note the **External Logins: 0** associated with this account.

Click the link to another log in service and accept the app requests. The two accounts have been combined, you will be able to log on with either account. You might want your users to add local accounts in case their social log in authentication service is down, or more likely they have lost access to their social account.

In the following image, Tom is a social log in (which you can see from the **External Logins: 1** shown on the page).

Clicking on **Pick a password** allows you to add a local log on associated with the same account.

Email confirmation in more depth

My tutorial Account Confirmation and Password Recovery with ASP.NET Identity goes into this topic with more details.

Debugging the app

If you don't get an email containing the link:

- Check your junk or spam folder.
- Log into your SendGrid account and click on the Email Activity link.

To test the verification link without email, download the completed sample. The confirmation link and

confirmation codes will be displayed on the page.

- Account Confirmation and Password Recovery with ASP.NET Identity Goes into more detail on password recovery and account confirmation.
- MVC 5 App with Facebook, Twitter, LinkedIn and Google OAuth2 Sign-on This tutorial shows you how to write an ASP.NET MVC 5 app with Facebook and Google OAuth 2 authorization. It also shows how to add additional data to the Identity database.
- Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL Database to Azure. This tutorial adds Azure deployment, how to secure your app with roles, how to use the membership API to add users and roles, and additional security features.
- Creating a Google app for OAuth 2 and connecting the app to the project
- Creating the app in Facebook and connecting the app to the project
- Setting up SSL in the Project

ASP.NET MVC 5 app with SMS and email Two-Factor Authentication

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

> This tutorial shows you how to build an ASP.NET MVC 5 web app with Two-Factor Authentication. You should complete Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset before proceeding. You can download the completed application here. The download contains debugging helpers that let you test email confirmation and SMS without setting up an email or SMS provider.
>
> This tutorial was written by Rick Anderson (Twitter: @RickAndMSFT).

- Create an ASP.NET MVC app
- Set up SMS for Two-factor authentication
- Enable Two-factor authentication
- Additional Resources

Create an ASP.NET MVC app

Start by installing and running Visual Studio Express 2013 for Web or Visual Studio 2013. Install Visual Studio 2013 Update 3 or higher.

> **NOTE**
>
> Warning: You should complete Create a secure ASP.NET MVC 5 web app with log in, email confirmation and password reset before proceeding. You must install Visual Studio 2013 Update 3 or higher to complete this tutorial.

1. Create a new ASP.NET Web project and select the MVC template. Web Forms also supports ASP.NET Identity, so you could follow similar steps in a web forms app.

2. Leave the default authentication as **Individual User Accounts**. If you'd like to host the app in Azure, leave the check box checked. Later in the tutorial we will deploy to Azure. You can open an Azure account for free.
3. Set the project to use SSL.

Set up SMS for Two-factor authentication

This tutorial provides instructions for using either Twilio or ASPSMS but you can use any other SMS provider.

1. **Creating a User Account with an SMS provider**

   Create a Twilio or an ASPSMS account.

2. **Installing additional packages or adding service references**

   Twilio:
   In the Package Manager Console, enter the following command:
   `Install-Package Twilio`

   ASPSMS:
   The following service reference needs to be added:

Address:
`https://webservice.aspsms.com/aspsmsx2.asmx?WSDL`

Namespace:
`ASPSMSX2`

3. **Figuring out SMS Provider User credentials**

   Twilio:
   From the **Dashboard** tab of your Twilio account, copy the **Account SID** and **Auth token**.

   ASPSMS:
   From your account settings, navigate to **Userkey** and copy it together with your self-defined **Password**.

   We will later store these values in the *web.config* file within the keys `"SMSAccountIdentification"` and `"SMSAccountPassword"` .

4. **Specifying SenderID / Originator**

   Twilio:
   From the **Numbers** tab, copy your Twilio phone number.

   ASPSMS:
   Within the **Unlock Originators** Menu, unlock one or more Originators or choose an alphanumeric Originator (Not supported by all networks).

   We will later store this value in the *web.config* file within the key `"SMSAccountFrom"` .

5. **Transferring SMS provider credentials into app**

   Make the credentials and sender phone number available to the app. To keep things simple we will store these values in the *web.config* file. When we deploy to Azure, we can store the values securely in the **app settings** section on the web site configure tab.

```
</connectionStrings>
   <appSettings>
      <add key="webpages:Version" value="3.0.0.0" />
      <!-- Markup removed for clarity. -->
      <!-- SendGrid-->
      <add key="mailAccount" value="account" />
      <add key="mailPassword" value="password" />
      <add key="SMSAccountIdentification" value="My Identification" />
      <add key="SMSAccountPassword" value="My Password" />
      <add key="SMSAccountFrom" value="+12065551234" />
   </appSettings>
  <system.web>
```

WARNING

Security - Never store sensitive data in your source code. The account and credentials are added to the code above to keep the sample simple. See Best practices for deploying passwords and other sensitive data to ASP.NET and Azure.

6. **Implementation of data transfer to SMS provider**

   Configure the `SmsService` class in the *App_Start\IdentityConfig.cs* file.

   Depending on the used SMS provider activate either the **Twilio** or the **ASPSMS** section:

```
public class SmsService : IIdentityMessageService
{
    public Task SendAsync(IdentityMessage message)
    {
        // Twilio Begin
        //var accountSid = ConfigurationManager.AppSettings["SMSAccountIdentification"];
        //var authToken = ConfigurationManager.AppSettings["SMSAccountPassword"];
        //var fromNumber = ConfigurationManager.AppSettings["SMSAccountFrom"];

        //TwilioClient.Init(accountSid, authToken);

        //MessageResource result = MessageResource.Create(
            //new PhoneNumber(message.Destination),
            //from: new PhoneNumber(fromNumber),
           //body: message.Body
        //);

        ////Status is one of Queued, Sending, Sent, Failed or null if the number is not valid
         //Trace.TraceInformation(result.Status.ToString());
        ////Twilio doesn't currently have an async API, so return success.
         //return Task.FromResult(0);
        // Twilio End

        // ASPSMS Begin
        // var soapSms = new MvcPWx.ASPSMSX2.ASPSMSX2SoapClient("ASPSMSX2Soap");
        // soapSms.SendSimpleTextSMS(
        //   System.Configuration.ConfigurationManager.AppSettings["SMSAccountIdentification"],
        //   System.Configuration.ConfigurationManager.AppSettings["SMSAccountPassword"],
        //   message.Destination,
        //   System.Configuration.ConfigurationManager.AppSettings["SMSAccountFrom"],
        //   message.Body);
        // soapSms.Close();
        // return Task.FromResult(0);
        // ASPSMS End
    }
}
```

7. Update the *Views\Manage\Index.cshtml* Razor view: (note: don't just remove the comments in the exiting code, use the code below.)

```
@model MvcPWy.Models.IndexViewModel
@{
   ViewBag.Title = "Manage";
}
<h2>@ViewBag.Title.</h2>
<p class="text-success">@ViewBag.StatusMessage</p>
<div>
   <h4>Change your account settings</h4>
   <hr />
   <dl class="dl-horizontal">
      <dt>Password:</dt>
      <dd>
         [
         @if (Model.HasPassword)
         {
            @Html.ActionLink("Change your password", "ChangePassword")
         }
         else
         {
            @Html.ActionLink("Create", "SetPassword")
         }
         ]
      </dd>
      <dt>External Logins:</dt>
      <dd>
         @Model.Logins.Count [
         @Html.ActionLink("Manage", "ManageLogins") ]
      </dd>
        <dt>Phone Number:</dt>
      <dd>
         @(Model.PhoneNumber ?? "None") [
         @if (Model.PhoneNumber != null)
         {
            @Html.ActionLink("Change", "AddPhoneNumber")
            @:  | 
            @Html.ActionLink("Remove", "RemovePhoneNumber")
         }
         else
         {
            @Html.ActionLink("Add", "AddPhoneNumber")
         }
         ]
      </dd>
      <dt>Two-Factor Authentication:</dt>
      <dd>
         @if (Model.TwoFactor)
         {
            using (Html.BeginForm("DisableTwoFactorAuthentication", "Manage", FormMethod.Post, new {
@class = "form-horizontal", role = "form" }))
            {
               @Html.AntiForgeryToken()
               <text>Enabled
                  <input type="submit" value="Disable" class="btn btn-link" />
               </text>
            }
         }
         else
         {
            using (Html.BeginForm("EnableTwoFactorAuthentication", "Manage", FormMethod.Post, new {
@class = "form-horizontal", role = "form" }))
            {
               @Html.AntiForgeryToken()
               <text>Disabled
                  <input type="submit" value="Enable" class="btn btn-link" />
               </text>
```

```
                </text>
            }
        }
    </dd>
  </dl>
</div>
```

8. Verify the `EnableTwoFactorAuthentication` and `DisableTwoFactorAuthentication` action methods in the `ManageController` have the[ValidateAntiForgeryToken] attribute:

```
//
// POST: /Manage/EnableTwoFactorAuthentication
[HttpPost,ValidateAntiForgeryToken]
public async Task<ActionResult> EnableTwoFactorAuthentication()
{
    await UserManager.SetTwoFactorEnabledAsync(User.Identity.GetUserId(), true);
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", "Manage");
}
//
// POST: /Manage/DisableTwoFactorAuthentication
[HttpPost, ValidateAntiForgeryToken]
public async Task<ActionResult> DisableTwoFactorAuthentication()
{
    await UserManager.SetTwoFactorEnabledAsync(User.Identity.GetUserId(), false);
    var user = await UserManager.FindByIdAsync(User.Identity.GetUserId());
    if (user != null)
    {
        await SignInAsync(user, isPersistent: false);
    }
    return RedirectToAction("Index", "Manage");
}
```

9. Run the app and log in with the account you previously registered.

10. Click on your User ID, which activates the `Index` action method in `Manage` controller.

11. Click Add.

12. The `AddPhoneNumber` action method displays a dialog box to enter a phone number that can receive SMS messages.

```
// GET: /Account/AddPhoneNumber
public ActionResult AddPhoneNumber()
{
   return View();
}
```

13. In a few seconds you will get a text message with the verification code. Enter it and press **Submit**.

14. The Manage view shows your phone number was added.

Enable two-factor authentication

In the template generated app, you need to use the UI to enable two-factor authentication (2FA). To enable 2FA, click on your user ID (email alias) in the navigation bar.

Click on enable 2FA.

Logout, then log back in. If you've enabled email (see my previous tutorial), you can select the SMS or email for 2FA.

The Verify Code page is displayed where you can enter the code (from SMS or email).

Clicking on the **Remember this browser** check box will exempt you from needing to use 2FA to log in when using the browser and device where you checked the box. As long as malicious users can't gain access to your device, enabling 2FA and clicking on the **Remember this browser** will provide you with convenient one step password access, while still retaining strong 2FA protection for all access from non-trusted devices. You can do this on any private device you regularly use.

This tutorial provides a quick introduction to enabling 2FA on a new ASP.NET MVC app. My tutorial Two-factor authentication using SMS and email with ASP.NET Identity goes into detail on the code behind the sample.

XSRF/CSRF Prevention in ASP.NET MVC and Web Pages

2/20/2020 • 15 minutes to read • Edit Online

by Rick Anderson

Cross-site request forgery (also known as XSRF or CSRF) is an attack against web-hosted applications whereby a malicious web site can influence the interaction between a client browser and a web site trusted by that browser. These attacks are made possible because web browsers will send authentication tokens automatically with every request to a web site. The canonical example is an authentication cookie, such as ASP.NET's Forms Authentication ticket. However, web sites which use any persistent authentication mechanism (such as Windows Authentication, Basic, and so forth) can be targeted by these attacks.

An XSRF attack is distinct from a phishing attack. Phishing attacks require interaction from the victim. In a phishing attack, a malicious web site will mimic the target web site, and the victim is fooled into providing sensitive information to the attacker. In an XSRF attack, there is often no interaction necessary from the victim. Rather, the attacker is relying on the browser automatically sending all relevant cookies to the destination web site.

For more information, see the Open Web Application Security Project(OWASP) XSRF.

Anatomy of an attack

To walk through an XSRF attack, consider a user who wants to perform some online banking transactions. This user first visits WoodgroveBank.com and logs in, at which point the response header will contain her authentication cookie:

```
HTTP/1.1 200 OK
Date: Mon, 18 Jun 2012 21:22:33 GMT
X-AspNet-Version: 4.0.30319
Set-Cookie: .ASPXAUTH={authentication-token}; path=/; secure; HttpOnly;
{ Cache-Control, Content-Type, Location, Server and other keys/values not listed. }
```

Because the authentication cookie is a session cookie, it will be automatically cleared by the browser when the browser process exits. However, until that time, the browser will automatically include the cookie with each request to WoodgroveBank.com. The user now wants to transfer $1000 to another account, so she fills out a form on the banking site, and the browser makes this request to the server:

```
POST /DoTransfer HTTP/1.1
Host: WoodgroveBank.com
Content-Type: application/x-www-form-urlencoded
Cookie: .ASPXAUTH={authentication-token}
toAcct=12345&amount=1,000.00
```

Because this operation has a side effect (it initiates a monetary transaction), the banking site has chosen to require an HTTP POST in order to initiate this operation. The server reads the authentication token from the request, looks up the current user's account number, verifies that sufficient funds exist, and then initiates the transaction into the destination account.

Her online banking complete, the user navigates away from the banking site and visits other locations on the

web. One of those sites – fabrikam.com – includes the following markup on a page embedded within an <iframe>:

```
<form id="theForm" action="https://WoodgroveBank.com/DoTransfer" method="post">
    <input type="hidden" name="toAcct" value="67890" />
    <input type="hidden" name="amount" value="250.00" />
</form>
<script type="text/javascript">
    document.getElementById('theForm').submit();
</script>
```

Which then causes the browser to make this request:

```
POST /DoTransfer HTTP/1.1
Host: WoodgroveBank.com
Content-Type: application/x-www-form-urlencoded
Cookie: .ASPXAUTH={authentication-token}
toAcct=67890&amount=250.00
```

The attacker is exploiting the fact that the user might still have a valid authentication token for the target web site, and she is using a small snippet of Javascript to cause the browser to make an HTTP POST to the target site automatically. If the authentication token is still valid, the banking site will initiate a transfer of $250 into the account of the attacker's choosing.

Ineffective mitigations

It is interesting to note that in the above scenario, the fact that WoodgroveBank.com was being accessed via SSL and had an SSL-only authentication cookie was insufficient to thwart the attack. The attacker is able to specify the URI scheme (https) in her <form> element, and the browser will continue to send unexpired cookies to the target site as long as those cookies are consistent with the URI scheme of the intended target.

One could argue that the user should simply not visit untrusted sites, as visiting only trusted sites is helps to remain safe online. There is some truth to this, but unfortunately this advice is not always practical. Perhaps the user "trusts" the local news site ConsolidatedMessenger. ConsolidatedMessenger.com and goes to visit that site instead, but that site has an XSS vulnerability which allows an attacker to inject the same snippet of code that was running on fabrikam.com.

You can verify that incoming requests have a Referer header referencing your domain. This will stop requests unwittingly submitted from a third-party domain. However, some people disable their browser's Referer header for privacy reasons, and attackers can sometimes spoof that header if the victim has certain insecure software installed. Verifying the Referer header is not considered a secure approach to preventing XSRF attacks.

Web Stack Runtime XSRF mitigations

The ASP.NET Web Stack Runtime uses a variant of the synchronizer token pattern to defend against XSRF attacks. The general form of the synchronizer token pattern is that two anti-XSRF tokens are submitted to the server with each HTTP POST (In addition to the authentication token): one token as a cookie, and the other as a form value. The token values generated by the ASP.NET runtime are not deterministic or predictable by an attacker. When the tokens are submitted, the server will allow the request to proceed only if both tokens pass a comparison check.

The XSRF request verification *session token* is stored as an HTTP cookie and currently contains the following information in its payload:

- A security token, consisting of a random 128-bit identifier.
  The following image shows the XSRF request verification session token displayed with the Internet Explorer F12 developer tools: (Note this is the current implementation and is subject, even likely, to change.)

The *field token* is stored as an `<input type="hidden" />` and contains the following information in its payload:

- The logged-in user's username (if authenticated).
- Any additional data provided by an IAntiForgeryAdditionalDataProvider.

The payloads of the anti-XSRF tokens are encrypted and signed, so you can't view the username when using tools to examine the tokens. When the web application is targeting ASP.NET 4.0, cryptographic services are provided by the MachineKey.Encode routine. When the web application is targeting ASP.NET 4.5 or higher, cryptographic services are provided by the MachineKey.Protect routine, which offers better performance, extensibility, and security. See the following blog posts for more details:

- Cryptographic Improvements in ASP.NET 4.5, pt. 1
- Cryptographic Improvements in ASP.NET 4.5, pt. 2
- Cryptographic Improvements in ASP.NET 4.5, pt. 3

Generating the tokens

To generate the anti-XSRF tokens, call the @Html.AntiForgeryToken method from an MVC view or @AntiForgery.GetHtml() from a Razor page. The runtime will then perform the following steps:

1. If the current HTTP request already contains an anti-XSRF session token (the anti-XSRF cookie __RequestVerificationToken), the security token is extracted from it. If the HTTP request does not contain an anti-XSRF session token or if extraction of the security token fails, a new random anti-XSRF token will be generated.
2. An anti-XSRF field token is generated using the security token from step (1) above and the identity of the current logged-in user. (For more information on determining user identity, see the **Scenarios with special support** section below.) Additionally, if an IAntiForgeryAdditionalDataProvider is configured, the runtime will call its GetAdditionalData method and include the returned string in the field token. (See the **Configuration and extensibility** section for more information.)
3. If a new anti-XSRF token was generated in step (1), a new session token will be created to contain it and will be added to the outbound HTTP cookies collection. The field token from step (2) will be wrapped in an `<input type="hidden" />` element, and this HTML markup will be the return value of `Html.AntiForgeryToken()` or `AntiForgery.GetHtml()`.

Validating the tokens

To validate the incoming anti-XSRF tokens, the developer includes a ValidateAntiForgeryToken attribute on her MVC action or controller, or she calls `@AntiForgery.Validate()` from her Razor page. The runtime will perform the following steps:

1. The incoming session token and field token are read and the anti-XSRF token extracted from each. The anti-

XSRF tokens must be identical per step (2) in the generation routine.

2. If the current user is authenticated, her username is compared with the username stored in the field token. The usernames must match.
3. If an IAntiForgeryAdditionalDataProvider is configured, the runtime calls its *ValidateAdditionalData* method. The method must return the Boolean value *true*.

If validation succeeds, the request is allowed to proceed. If validation fails, the framework will throw an *HttpAntiForgeryException*.

Failure conditions

Starting with The ASP.NET Web Stack Runtime v2, any *HttpAntiForgeryException* that is thrown during validation will contain detailed information about what went wrong. The currently defined failure conditions are:

- The session token or form token is not present in the request.
- The session token or form token is unreadable. The most likely cause of this is a farm running mismatched versions of The ASP.NET Web Stack Runtime or a farm where the <machineKey> element in Web.config differs between machines. You can use a tool such as Fiddler to force this exception by tampering with either anti-XSRF token.
- The session token and field token were swapped.
- The session token and field token contain mismatched security tokens.
- The username embedded within the field token does not match the current logged-in user's username.
- The *IAntiForgeryAdditionalDataProvider.ValidateAdditionalData* method returned *false*.

The anti-XSRF facilities may also perform additional checking during token generation or validation, and failures during these checks may result in exceptions being thrown. See the WIF / ACS / claims-based authentication and **Configuration and extensibility** sections for more information.

Scenarios with special support

Anonymous authentication

The anti-XSRF system contains special support for anonymous users, where "anonymous" is defined as a user where the *IIdentity.IsAuthenticated* property returns *false*. Scenarios include providing XSRF protection to the login page (before the user is authenticated) and custom authentication schemes where the application uses a mechanism other than *IIdentity* to identify users.

To support these scenarios, recall that the session and field tokens are joined by a security token, which is a 128-bit randomly-generated opaque identifier. This security token is used to track an individual user's session as she navigates the site, so it effectively serves the purpose of an anonymous identifier. An empty string is used in place of the username for the generation and validation routines described above.

WIF / ACS / claims-based authentication

Normally, the *IIdentity* classes built in to the .NET Framework have the property that *IIdentity.Name* is sufficient to uniquely identify a particular user within a particular application. For example, *FormsIdentity.Name* returns the username stored in the membership database (which is unique for all applications depending on that database), *WindowsIdentity.Name* returns the domain-qualified identity of the user, and so on. These systems provide not only authentication; they also *identify* users to an application.

Claims-based authentication, on the other hand, does not necessarily require identifying a particular user. Instead, the *ClaimsPrincipal* and *ClaimsIdentity* types are associated with a set of *Claim* instances, where the individual claims might be "is 18+ years of age" or "is an administrator" to anything else. Since the user hasn't necessarily been identified, the runtime cannot use the *ClaimsIdentity.Name* property as a unique identifier for this particular user. The team has seen real-world examples where *ClaimsIdentity.Name* returns *null*, returns a friendly (display) name, or otherwise returns a string that isn't appropriate for use as a unique identifier for the

user.

Many of deployments which use claims-based authentication are using Azure Access Control Service (ACS) in particular. ACS allows the developer to configure individual *identity providers* (such as ADFS, the Microsoft Account provider, OpenID providers like Yahoo!, etc.), and the identity providers return *name identifiers*. These name identifiers may contain Personally Identifiable Information (PII) like an email address, or they could be anonymized like a Private Personal Identifier (PPID). Regardless, the tuple (identity provider, name identifier) sufficiently serves as an appropriate tracking token for a particular user while she is browsing the site, so the ASP.NET Web Stack Runtime can use the tuple in place of the username when generating and validating anti-XSRF field tokens. The particular URIs for the identity provider and the name identifier are :

- `https://schemas.microsoft.com/accesscontrolservice/2010/07/claims/identityprovider`
- `http://schemas.xmlsoap.org/ws/2005/05/identity/claims/nameidentifier`

(see this ACS doc page for more info.)

When generating or validating a token, the ASP.NET Web Stack Runtime will at runtime try binding to the types:

- `Microsoft.IdentityModel.Claims.IClaimsIdentity, Microsoft.IdentityModel, Version=3.5.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35`
  (For the WIF SDK.)
- `System.Security.Claims.ClaimsIdentity` (For .NET 4.5).

If these types exist, and if the current user's *IIIIdentity* implements or subclasses one of these types, the anti-XSRF facility will use the (identity provider, name identifier) tuple in place of the username when generating and validating the tokens. If no such tuple is present, the request will fail with an error describing to the developer how to configure the anti-XSRF system to understand the particular claims-based authentication mechanism in use. See the **Configuration and extensibility** section for more information.

OAuth / OpenID authentication

Finally, the anti-XSRF facility has special support for applications which use OAuth or OpenID authentication. This support is heuristic-based: if the current *IIdentity.Name* begins with http:// or https://, then username comparisons will be done using an Ordinal comparer rather than the default OrdinalIgnoreCase comparer.

Configuration and extensibility

Occasionally, developers may want tighter control over the anti-XSRF generation and validation behaviors. For example, perhaps the MVC and Web Pages helpers' default behavior of automatically adding HTTP cookies to the response is undesirable, and the developer may wish to persist the tokens elsewhere. There exist two APIs to assist with this:

```
AntiForgery.GetTokens(string oldCookieToken, out string newCookieToken, out string formToken);
AntiForgery.Validate(string cookieToken, string formToken);
```

The *GetTokens* method takes as input an existing XSRF request verification session token (which may be null) and produces as output a new XSRF request verification session token and field token. The tokens are simply opaque strings with no decoration; the *formToken* value will for instance not be wrapped in an <input> tag. The *newCookieToken* value may be null; if this occurs, then the *oldCookieToken* value is still valid and no new response cookie need be set. The caller of *GetTokens* is responsible for persisting any necessary response cookies or generating any necessary markup; the *GetTokens* method itself will not alter the response as a side effect. The *Validate* method takes the incoming session and field tokens and runs the aforementioned validation logic over them.

AntiForgeryConfig

The developer may configure the anti-XSRF system from Application_Start. Configuration is programmatic. The properties of the static *AntiForgeryConfig* type are described below. Most users using claims will want to set the

UniqueClaimTypeIdentifier property.

PROPERTY	DESCRIPTION
AdditionalDataProvider	An IAntiForgeryAdditionalDataProvider that provides additional data during token generation and consumes additional data during token validation. The default value is *null*. For more information, see the IAntiForgeryAdditionalDataProvider section.
CookieName	A string that provides the name of the HTTP cookie that is used to store the anti-XSRF session token. If this value is not set, a name will be automatically generated based on the application's deployed virtual path. The default value is *null*.
RequireSsl	A Boolean that dictates whether the anti-XSRF tokens are required to be submitted over an SSL-secured channel. If this value is *true*, any automatically-generated cookies will have the "secure" flag set, and the anti-XSRF APIs will throw if called from within a request that is not submitted via SSL. The default value is *false*.
SuppressIdentityHeuristicChecks	A Boolean that dictates whether the anti-XSRF system should deactivate its support for claims-based identities. If this value is *true*, the system will assume that *IIdentity.Name* is appropriate for use as a unique per-user identifier and will not try to special-case *IClaimsIdentity* or *ClClaimsIdentity* as described in the WIF / ACS / claims-based authentication section. The default value is `false`.
UniqueClaimTypeIdentifier	A string that indicates which claim type is appropriate for use as a unique per-user identifier. If this value is set and the current *IIdentity* is claims-based, the system will attempt to extract a claim of the type specified by *UniqueClaimTypeIdentifier*, and the corresponding value will be used in place of the user's username when generating the field token. If the claim type is not found, the system will fail the request. The default value is *null*, which indicates that the system should use the (identity provider, name identifier) tuple as previously described in place of the user's username.

IAntiForgeryAdditionalDataProvider

The *IAntiForgeryAdditionalDataProvider* type allows developers to extend the behavior of the anti-XSRF system by round-tripping additional data in each token. The *GetAdditionalData* method is called each time a field token is generated, and the return value is embedded within the generated token. An implementer could return a timestamp, a nonce, or any other value she wishes from this method.

Similarly, the *ValidateAdditionalData* method is called each time a field token is validated, and the "additional data" string that was embedded within the token is passed to the method. The validation routine could implement a timeout (by checking the current time against the time that was stored when the token was created), a nonce checking routine, or any other desired logic.

Design decisions and security considerations

The security token that links the session and field tokens is technically only necessary when trying to protect anonymous / unauthenticated users against XSRF attacks. When the user is authenticated, the authentication token itself (presumably submitted in the form of a cookie) could be used as one half of a synchronizer token pair. However, there are valid scenarios for protecting login pages hit by unauthenticated users, and the anti-XSRF

logic was made simpler by always generating and validating the security token, even for authenticated users. It also does provide some additional protection in the event that a field token is ever compromised by an attacker, as setting or guessing the session token would be another hurdle for the attacker to overcome.

Developers should use caution when multiple applications are hosted in a single domain. For example, even though *example1.cloudapp.net* and *example2.cloudapp.net* are different hosts, there is an implicit trust relationship between all hosts under the **.cloudapp.net* domain. This implicit trust relationship allows potentially untrusted hosts to affect each other's cookies (the same-origin policies that govern AJAX requests do not necessarily apply to HTTP cookies). The ASP.NET Web Stack Runtime provides some mitigation in that the username is embedded into the field token, so even if a malicious subdomain is able to overwrite a session token it will be unable to generate a valid field token for the user. However, when hosted in such an environment the built-in anti-XSRF routines still cannot defend against session hijacking or login XSRF.

The anti-XSRF routines currently do not defend against clickjacking. Applications that wish to defend themselves against clickjacking may easily do so by sending an X-Frame-Options: SAMEORIGIN header with each response. This header is supported by all recent browsers. For more information, see the IE blog, the SDL blog, and OWASP. The ASP.NET Web Stack Runtime may in some future release make the MVC and Web Pages anti-XSRF helpers automatically set this header so that applications are automatically protected against this attack.

Web developers should continue to ensure that their site is not vulnerable to XSS attacks. XSS attacks are very powerful, and a successful exploit would also break the ASP.NET Web Stack Runtime defenses against XSRF attacks.

Preventing Open Redirection Attacks (C#)

2/20/2020 • 7 minutes to read • Edit Online

by Jon Galloway

This tutorial explains how you can prevent open redirection attacks in your ASP.NET MVC applications. This tutorial discusses the changes that have been made in the AccountController in ASP.NET MVC 3 and demonstrates how you can apply these changes in your existing ASP.NET MVC 1.0 and 2 applications.

What is an Open Redirection Attack?

Any web application that redirects to a URL that is specified via the request such as the querystring or form data can potentially be tampered with to redirect users to an external, malicious URL. This tampering is called an open redirection attack.

Whenever your application logic redirects to a specified URL, you must verify that the redirection URL hasn't been tampered with. The login used in the default AccountController for both ASP.NET MVC 1.0 and ASP.NET MVC 2 is vulnerable to open redirection attacks. Fortunately, it is easy to update your existing applications to use the corrections from the ASP.NET MVC 3 Preview.

To understand the vulnerability, let's look at how the login redirection works in a default ASP.NET MVC 2 Web Application project. In this application, attempting to visit a controller action that has the [Authorize] attribute will redirect unauthorized users to the /Account/LogOn view. This redirect to /Account/LogOn will include a returnUrl querystring parameter so that the user can be returned to the originally requested URL after they have successfully logged in.

In the screenshot below, we can see that an attempt to access the /Account/ChangePassword view when not logged in results in a redirect to /Account/LogOn?ReturnUrl=%2fAccount%2fChangePassword%2f.

Figure 01: Login page with an open redirection

Since the ReturnUrl querystring parameter is not validated, an attacker can modify it to inject any URL address into the parameter to conduct an open redirection attack. To demonstrate this, we can modify the ReturnUrl parameter to http://bing.com, so the resulting login URL will be /Account/LogOn?ReturnUrl=http://www.bing.com/. Upon successfully logging in to the site, we are redirected to http://bing.com. Since this redirection is not validated, it could instead point to a malicious site that attempts to trick the user.

A more complex Open Redirection Attack

Open redirection attacks are especially dangerous because an attacker knows that we're trying to log into a specific website, which makes us vulnerable to a phishing attack. For example, an attacker could send malicious emails to website users in an attempt to capture their passwords. Let's look at how this would work on the NerdDinner site. (Note that the live NerdDinner site has been updated to protect against open redirection attacks.)

First, an attacker sends us a link to the login page on NerdDinner that includes a redirect to their forged page:

http://nerddinner.com/Account/LogOn?returnUrl=http://nerddiner.com/Account/LogOn

Note that the return URL points to nerddiner.com, which is missing an "n" from the word dinner. In this example, this is a domain that the attacker controls. When we access the above link, we're taken to the legitimate NerdDinner.com login page.

Figure 02: NerdDinner login page with an open redirection

When we correctly log in, the ASP.NET MVC AccountController's LogOn action redirects us to the URL specified in the returnUrl querystring parameter. In this case, it's the URL that the attacker has entered, which is http://nerddiner.com/Account/LogOn. Unless we're extremely watchful, it's very likely we won't notice this, especially because the attacker has been careful to make sure that their forged page looks exactly like the legitimate login page. This login page includes an error message requesting that we login again. Clumsy us, we must have mistyped our password.

Figure 03: Forged NerdDinner Login screen

When we retype our user name and password, the forged login page saves the information and sends us back to the legitimate NerdDinner.com site. At this point, the NerdDinner.com site has already authenticated us, so the forged login page can redirect directly to that page. The end result is that the attacker has our user name and password, and we are unaware that we've provided it to them.

Looking at the vulnerable code in the AccountController LogOn Action

The code for the LogOn action in an ASP.NET MVC 2 application is shown below. Note that upon a successful login, the controller returns a redirect to the returnUrl. You can see that no validation is being performed against the returnUrl parameter.

Listing 1 – ASP.NET MVC 2 LogOn action in `AccountController.cs`

```
[HttpPost]
public ActionResult LogOn(LogOnModel model, string returnUrl)
{
    if (ModelState.IsValid)
    {
        if (MembershipService.ValidateUser(model.UserName, model.Password))
        {
            FormsService.SignIn(model.UserName, model.RememberMe);
            if (!String.IsNullOrEmpty(returnUrl))
            {
                return Redirect(returnUrl);
            }
            else
            {
                return RedirectToAction("Index", "Home");
            }
        }
        else
        {
            ModelState.AddModelError("", "The user name or password provided is incorrect.");
        }
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

Now let's look at the changes to the ASP.NET MVC 3 LogOn action. This code has been changed to validate the returnUrl parameter by calling a new method in the System.Web.Mvc.Url helper class named `IsLocalUrl()`.

Listing 2 – ASP.NET MVC 3 LogOn action in `AccountController.cs`

```
[HttpPost]
public ActionResult LogOn(LogOnModel model, string returnUrl)
{
    if (ModelState.IsValid)
    {
        if (MembershipService.ValidateUser(model.UserName, model.Password))
        {
            FormsService.SignIn(model.UserName, model.RememberMe);
            if (Url.IsLocalUrl(returnUrl))
            {
                return Redirect(returnUrl);
            }
            else
            {
                return RedirectToAction("Index", "Home");
            }
        }
        else
        {
            ModelState.AddModelError("",
        "The user name or password provided is incorrect.");
        }
    }

    // If we got this far, something failed, redisplay form
    return View(model);
}
```

This has been changed to validate the return URL parameter by calling a new method in the System.Web.Mvc.Url helper class, `IsLocalUrl()`.

Protecting Your ASP.NET MVC 1.0 and MVC 2 Applications

We can take advantage of the ASP.NET MVC 3 changes in our existing ASP.NET MVC 1.0 and 2 applications by adding the IsLocalUrl() helper method and updating the LogOn action to validate the returnUrl parameter.

The UrlHelper IsLocalUrl() method actually just calling into a method in System.Web.WebPages, as this validation is also used by ASP.NET Web Pages applications.

Listing 3 – The IsLocalUrl() method from the ASP.NET MVC 3 UrlHelper `class`

```
public bool IsLocalUrl(string url) {
    return System.Web.WebPages.RequestExtensions.IsUrlLocalToHost(
        RequestContext.HttpContext.Request, url);
}
```

The IsUrlLocalToHost method contains the actual validation logic, as shown in Listing 4.

Listing 4 – IsUrlLocalToHost() method from the System.Web.WebPages RequestExtensions class

```
public static bool IsUrlLocalToHost(this HttpRequestBase request, string url)
{
   return !url.IsEmpty() &&
          ((url[0] == '/' && (url.Length == 1 ||
           (url[1] != '/' && url[1] != '\\'))) ||   // "/" or "/foo" but not "//" or "/\"
           (url.Length > 1 &&
            url[0] == '~' && url[1] == '/'));   // "~/" or "~/foo"
}
```

In our ASP.NET MVC 1.0 or 2 application, we'll add a IsLocalUrl() method to the AccountController, but you're encouraged to add it to a separate helper class if possible. We will make two small changes to the ASP.NET MVC 3 version of IsLocalUrl() so that it will work inside the AccountController. First, we'll change it from a public method to a private method, since public methods in controllers can be accessed as controller actions. Second, we'll modify the call that checks the URL host against the application host. That call makes use of a local RequestContext field in the UrlHelper class. Instead of using this.RequestContext.HttpContext.Request.Url.Host, we will use this.Request.Url.Host. The following code shows the modified IsLocalUrl() method for use with a controller class in ASP.NET MVC 1.0 and 2 applications.

Listing 5 – IsLocalUrl() method, which is modified for use with an MVC Controller class

```
private bool IsLocalUrl(string url)
{
   if (string.IsNullOrEmpty(url))
   {
      return false;
   }
   else
   {
      return ((url[0] == '/' && (url.Length == 1 ||
              (url[1] != '/' && url[1] != '\\'))) ||   // "/" or "/foo" but not "//" or "/\"
              (url.Length > 1 &&
               url[0] == '~' && url[1] == '/'));   // "~/" or "~/foo"
   }
}
```

Now that the IsLocalUrl() method is in place, we can call it from our LogOn action to validate the returnUrl parameter, as shown in the following code.

Listing 6 – Updated LogOn method which validates the returnUrl parameter

```
[HttpPost]
public ActionResult LogOn(LogOnModel model, string returnUrl)
{
    if (ModelState.IsValid)
    {
        if (MembershipService.ValidateUser(model.UserName, model.Password))
        {
            FormsService.SignIn(model.UserName, model.RememberMe);
            if (IsLocalUrl(returnUrl))
            {
                return Redirect(returnUrl);
            }
            else
            {
                return RedirectToAction("Index", "Home");
            }
        }
        else
        {
            ModelState.AddModelError("",
            "The user name or password provided is incorrect.");
        }
    }
}
```

Now we can test an open redirection attack by attempting to log in using an external return URL. Let's use /Account/LogOn?ReturnUrl=http://www.bing.com/ again.

Figure 04: Testing the updated LogOn Action

After successfully logging in, we are redirected to the Home/Index Controller action rather than the external URL.

Figure 05: Open Redirection attack defeated

Summary

Open redirection attacks can occur when redirection URLs are passed as parameters in the URL for an application. The ASP.NET MVC 3 template includes code to protect against open redirection attacks. You can add this code with some modification to ASP.NET MVC 1.0 and 2 applications. To protect against open redirection attacks when logging into ASP.NET 1.0 and 2 applications, add a IsLocalUrl() method and validate the returnUrl parameter in the LogOn action.

Migrating ASP.NET MVC Applications to Windows Containers

4/6/2020 • 4 minutes to read • Edit Online

Running an existing .NET Framework-based application in a Windows container doesn't require any changes to your app. To run your app in a Windows container you create a Docker image containing your app and start the container. This topic explains how to take an existing ASP.NET MVC application and deploy it in a Windows container.

You start with an existing ASP.NET MVC app, then build the published assets using Visual Studio. You use Docker to create the image that contains and runs your app. You'll browse to the site running in a Windows container and verify the app is working.

This article assumes a basic understanding of Docker. You can learn about Docker by reading the Docker Overview.

The app you'll run in a container is a simple website that answers questions randomly. This app is a basic MVC application with no authentication or database storage; it lets you focus on moving the web tier to a container. Future topics will show how to move and manage persistent storage in containerized applications.

Moving your application involves these steps:

1. Creating a publish task to build the assets for an image.
2. Building a Docker image that will run your application.
3. Starting a Docker container that runs your image.
4. Verifying the application using your browser.

The finished application is on GitHub.

Prerequisites

The development machine must have the following software:

- Windows 10 Anniversary Update (or higher) or Windows Server 2016 (or higher)
- Docker for Windows - version Stable 1.13.0 or 1.12 Beta 26 (or newer versions)
- Visual Studio 2017

> **IMPORTANT**
>
> If you are using Windows Server 2016, follow the instructions for Container Host Deployment - Windows Server.

After installing and starting Docker, right-click on the tray icon and select **Switch to Windows containers**. This is required to run Docker images based on Windows. This command takes a few seconds to execute:

Publish script

Collect all the assets that you need to load into a Docker image in one place. You can use the Visual Studio **Publish** command to create a publish profile for your app. This profile will put all the assets in one directory tree that you copy to your target image later in this tutorial.

Publish Steps

1. Right click on the web project in Visual Studio, and select **Publish**.
2. Click the **Custom profile button**, and then select **File System** as the method.
3. Choose the directory. By convention, the downloaded sample uses `bin\Release\PublishOutput`.

Open the **File Publish Options** section of the **Settings** tab. Select **Precompile during publishing**. This optimization means that you'll be compiling views in the Docker container, you are copying the precompiled views.

Click **Publish**, and Visual Studio will copy all the needed assets to the destination folder.

Build the image

Create a new file named *Dockerfile* to define your Docker image. *Dockerfile* contains instructions to build the final image and includes any base image names, required components, the app you want to run, and other configuration images. *Dockerfile* is the input to the `docker build` command that creates the image.

For this exercise, you will build an image based on the `microsoft/aspnet` image located on Docker Hub. The base image, `microsoft/aspnet`, is a Windows Server image. It contains Windows Server Core, IIS, and ASP.NET 4.7.2. When you run this image in your container, it will automatically start IIS and installed websites.

The Dockerfile that creates your image looks like this:

```
# The `FROM` instruction specifies the base image. You are
# extending the `microsoft/aspnet` image.

FROM microsoft/aspnet

# The final instruction copies the site you published earlier into the container.
COPY ./bin/Release/PublishOutput/ /inetpub/wwwroot
```

There is no `ENTRYPOINT` command in this Dockerfile. You don't need one. When running Windows Server with IIS, the IIS process is the entrypoint, which is configured to start in the aspnet base image.

Run the Docker build command to create the image that runs your ASP.NET app. To do this, open a PowerShell window in the directory of your project and type the following command in the solution directory:

```
docker build -t mvcrandomanswers .
```

This command will build the new image using the instructions in your Dockerfile, naming (-t tagging) the image as mvcrandomanswers. This may include pulling the base image from Docker Hub, and then adding your app to that image.

Once that command completes, you can run the `docker images` command to see information on the new image:

```
REPOSITORY                    TAG                 IMAGE ID            CREATED             SIZE
mvcrandomanswers              latest              86838648aab6        2 minutes ago       10.1 GB
```

The IMAGE ID will be different on your machine. Now, let's run the app.

Start a container

Start a container by executing the following `docker run` command:

```
docker run -d --name randomanswers mvcrandomanswers
```

The `-d` argument tells Docker to start the image in detached mode. That means the Docker image runs disconnected from the current shell.

In many docker examples, you may see -p to map the container and host ports. The default aspnet image has already configured the container to listen on port 80 and expose it.

The `--name randomanswers` gives a name to the running container. You can use this name instead of the container ID in most commands.

The `mvcrandomanswers` is the name of the image to start.

Verify in the browser

Once the container starts, connect to the running container using `http://localhost` in the example shown. Type that URL into your browser, and you should see the running site.

> **NOTE**
> Some VPN or proxy software may prevent you from navigating to your site. You can temporarily disable it to make sure your container is working.

The sample directory on GitHub contains a PowerShell script that executes these commands for you. Open a PowerShell window, change directory to your solution directory, and type:

```
./run.ps1
```

The command above builds the image, displays the list of images on your machine, and starts a container.

To stop your container, issue a `docker stop` command:

```
docker stop randomanswers
```

To remove the container, issue a `docker rm` command:

```
docker rm randomanswers
```

ASP.NET MVC Performance

Profile and debug your ASP.NET MVC app with Glimpse

2/20/2020 • 5 minutes to read • Edit Online

by Rick Anderson

Glimpse is a thriving and growing family of open source NuGet packages that provides detailed performance, debugging and diagnostic information for ASP.NET apps. It's trivial to install, lightweight, ultra-fast, and displays key performance metrics at the bottom of every page. It allows you to drill down into your app when you need to find out what's going on at the server. Glimpse provides so much valuable information we recommend you use it throughout your development cycle, including your Azure test environment. While Fiddler and the F-12 development tools provide a client side view, Glimpse provides a detailed view from the server. This tutorial will focus on using the Glimpse ASP.NET MVC and EF packages, but many other packages are available. Where possible I will link to the appropriate Glimpse docs which I help maintain. Glimpse is an open source project, you too can contribute to the source code and the docs.

- Installing Glimpse
- Enable Glimpse for localhost
- The Timeline tab
- Model Binding
- Routes
- Using Glimpse on Azure
- Additional Resources

Installing Glimpse

You can install Glimpse from the NuGet package manager console or from the **Manage NuGet Packages** console. For this demo, I'll install the Mvc5 and EF6 packages:

Search for *Glimpse.EF*

By selecting **Installed packages**, you can see the Glimpse dependent modules installed:

The following commands install Glimpse MVC5 and EF6 modules from the package manager console:

```
PM> Install-Package Glimpse.MVC5
PM> Install-Package Glimpse.EF6
```

Enable Glimpse for localhost

Navigate to http://localhost:<port #>/glimpse.axd and click the **Turn Glimpse On** button.

If you have your favorites bar displayed, you can drag and drop the Glimpse buttons and add them as bookmarklets:

You can now navigate your app, and the **Heads Up Display** (HUD) is shown at the bottom of the page.

The Glimpse HUD page details the timing information shown above. The unobtrusive performance data the HUD displays can notify you of a problem immediately - before you get to the test cycle. Clicking on the "g" in the lower right corner brings up the Glimpse panel:

In the image above, the Execution tab is selected, which shows timing details of the actions and filters in the

pipeline. You can see my Stop Watch filter timer start at stage 6 of the pipeline. While my light weight timer can provide useful profile/timing data, it misses all the time spent in authorization and rendering the view. You can read about my timer at Profile and Time your ASP.NET MVC app all the way to Azure. The Tabs page provides links to detailed information on each tab.

The Timeline tab

I've modified Tom Dykstra's outstanding EF 6/MVC 5 tutorial with the following code change to the instructors controller:

```
public ActionResult Index(int? id, int? courseID, int ? eager)
{
    var viewModel = new InstructorIndexData();

    viewModel.Instructors = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses.Select(c => c.Department))
        .OrderBy(i => i.LastName);

    if (id != null)
    {
        ViewBag.InstructorID = id.Value;
        viewModel.Courses = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single().Courses;
    }

    if (courseID != null)
    {
       ViewBag.CourseID = courseID.Value;
       // Eager loading
       if (eager != null && eager > 0)
       {
          ViewBag.eagerMsg = "Eager Loading";

          viewModel.Enrollments = viewModel.Courses.Where(
              x => x.CourseID == courseID).Single().Enrollments;

       }
       else {
        // Explicit loading
          ViewBag.eagerMsg = "Explicit Loading";

        var selectedCourse = viewModel.Courses.Where(x => x.CourseID == courseID).Single();
        db.Entry(selectedCourse).Collection(x => x.Enrollments).Load();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            db.Entry(enrollment).Reference(x => x.Student).Load();
        }

        viewModel.Enrollments = selectedCourse.Enrollments;
       }
    }

    return View(viewModel);
}
```

The code above allows me to pass in query string (`eager`) to control eager or explicit loading of data. In the image below, explicit loading is used and the timing page shows each enrollment loaded in the `Index` action method:

In the following code, eager is specified, and each enrollment is fetched after the `Index` view is called:

You can hover over a time segment to get detailed timing information:

Model Binding

The model binding tab provides a wealth of information to help you understand how your form variables are bound and why some are not bound as would expect. The image below shows the **?** icon, which you can click on to bring up the glimpse help page for that feature.

Routes

The Glimpse Routes tab will can help you debug and understand routing. In the image below, the product route is selected (and it shows in green, a Glimpse convention).

Route constraints, Areas and data tokens are also displayed. See Glimpse Routes and Attribute Routing in ASP.NET MVC 5 for more information.

Using Glimpse on Azure

The Glimpse default security policy only allows Glimpse data to be displayed from local host. You can change this security policy so you can view this data on a remote server (such as a web app on Azure). For test environments on Azure, add the highlighted mark up to the bottom of the *web.config* file to enable Glimpse:

```
<glimpse defaultRuntimePolicy="On" endpointBaseUri="~/Glimpse.axd">
    <runtimePolicies>
      <ignoredTypes>
        <add type="Glimpse.AspNet.Policy.LocalPolicy, Glimpse.AspNet"/>
      </ignoredTypes>
    </runtimePolicies>
  </glimpse>
</configuration>
```

With this change alone, any user can see your Glimpse data on a remote site. Consider adding the markup above to a publish profile so it's only deployed an applied when you use that publish profile (for example, your Azure test profile.) To restrict Glimpse data, we will add the `canViewGlimpseData` role and only allow users in this role to view Glimpse data.

Remove the comments from the *GlimpseSecurityPolicy.cs* file and change the IsInRole call from `Administrator` to the `canViewGlimpseData` role:

```
public class GlimpseSecurityPolicy : IRuntimePolicy
{
    public RuntimePolicy Execute(IRuntimePolicyContext policyContext)
    {
        var httpContext = policyContext.GetHttpContext();
        if (!httpContext.User.IsInRole("canViewGlimpseData"))
        {
            return RuntimePolicy.Off;
        }

        return RuntimePolicy.On;
    }

    public RuntimeEvent ExecuteOn
    {
        get { return RuntimeEvent.EndRequest | RuntimeEvent.ExecuteResource; }
    }
}
```

WARNING

Security - The rich data provided by Glimpse could expose the security of your app. Microsoft has not performed a security audit of Glimpse for use on productions apps.

For information on adding roles, see my Deploy a Secure ASP.NET MVC 5 web app with Membership, OAuth, and SQL Database to Azure tutorial.

Using Asynchronous Methods in ASP.NET MVC 4

2/20/2020 • 12 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of building an asynchronous ASP.NET MVC Web application using Visual Studio Express 2012 for Web, which is a free version of Microsoft Visual Studio. You can also use Visual Studio 2012.
>
> A complete sample is provided for this tutorial on github https://github.com/RickAndMSFT/Async-ASP.NET/

The ASP.NET MVC 4 Controller class in combination .NET 4.5 enables you to write asynchronous action methods that return an object of type Task<ActionResult>. The .NET Framework 4 introduced an asynchronous programming concept referred to as a Task and ASP.NET MVC 4 supports Task. Tasks are represented by the **Task** type and related types in the System.Threading.Tasks namespace. The .NET Framework 4.5 builds on this asynchronous support with the await and async keywords that make working with Task objects much less complex than previous asynchronous approaches. The await keyword is syntactical shorthand for indicating that a piece of code should asynchronously wait on some other piece of code. The async keyword represents a hint that you can use to mark methods as task-based asynchronous methods. The combination of **await**, **async**, and the **Task** object makes it much easier for you to write asynchronous code in .NET 4.5. The new model for asynchronous methods is called the *Task-based Asynchronous Pattern* (**TAP**). This tutorial assumes you have some familiarity with asynchronous programing using await and async keywords and the Task namespace.

For more information on the using await and async keywords and the Task namespace, see the following references.

- Whitepaper: Asynchrony in .NET
- Async/Await FAQ
- Visual Studio Asynchronous Programming

How Requests Are Processed by the Thread Pool

On the web server, the .NET Framework maintains a pool of threads that are used to service ASP.NET requests. When a request arrives, a thread from the pool is dispatched to process that request. If the request is processed synchronously, the thread that processes the request is busy while the request is being processed, and that thread cannot service another request.

This might not be a problem, because the thread pool can be made large enough to accommodate many busy threads. However, the number of threads in the thread pool is limited (the default maximum for .NET 4.5 is 5,000). In large applications with high concurrency of long-running requests, all available threads might be busy. This condition is known as thread starvation. When this condition is reached, the web server queues requests. If the request queue becomes full, the web server rejects requests with an HTTP 503 status (Server Too Busy). The CLR thread pool has limitations on new thread injections. If concurrency is bursty (that is, your web site can suddenly get a large number of requests) and all available request threads are busy because of backend calls with high latency, the limited thread injection rate can make your application respond very poorly. Additionally, each new thread added to the thread pool has overhead (such as 1 MB of stack memory). A web application using synchronous methods to service high latency calls where the thread pool grows to the .NET 4.5 default maximum of 5, 000 threads would consume approximately 5 GB more memory than an application able the service the same requests using asynchronous methods and only 50 threads. When you're doing asynchronous work, you're not always using a thread. For example, when you make an asynchronous web service request, ASP.NET will not

be using any threads between the **async** method call and the **await**. Using the thread pool to service requests with high latency can lead to a large memory footprint and poor utilization of the server hardware.

Processing Asynchronous Requests

In a web app that sees a large number of concurrent requests at start-up or has a bursty load (where concurrency increases suddenly), making web service calls asynchronous increases the responsiveness of the app. An asynchronous request takes the same amount of time to process as a synchronous request. If a request makes a web service call that requires two seconds to complete, the request takes two seconds whether it's performed synchronously or asynchronously. However during an asynchronous call, a thread isn't blocked from responding to other requests while it waits for the first request to complete. Therefore, asynchronous requests prevent request queuing and thread pool growth when there are many concurrent requests that invoke long-running operations.

Choosing Synchronous or Asynchronous Action Methods

This section lists guidelines for when to use synchronous or asynchronous action methods. These are just guidelines; examine each application individually to determine whether asynchronous methods help with performance.

In general, use synchronous methods for the following conditions:

- The operations are simple or short-running.
- Simplicity is more important than efficiency.
- The operations are primarily CPU operations instead of operations that involve extensive disk or network overhead. Using asynchronous action methods on CPU-bound operations provides no benefits and results in more overhead.

In general, use asynchronous methods for the following conditions:

- You're calling services that can be consumed through asynchronous methods, and you're using .NET 4.5 or higher.
- The operations are network-bound or I/O-bound instead of CPU-bound.
- Parallelism is more important than simplicity of code.
- You want to provide a mechanism that lets users cancel a long-running request.
- When the benefit of switching threads outweighs the cost of the context switch. In general, you should make a method asynchronous if the synchronous method waits on the ASP.NET request thread while doing no work. By making the call asynchronous, the ASP.NET request thread is not stalled doing no work while it waits for the web service request to complete.
- Testing shows that the blocking operations are a bottleneck in site performance and that IIS can service more requests by using asynchronous methods for these blocking calls.

The downloadable sample shows how to use asynchronous action methods effectively. The sample provided was designed to provide a simple demonstration of asynchronous programming in ASP.NET MVC 4 using .NET 4.5. The sample is not intended to be a reference architecture for asynchronous programming in ASP.NET MVC. The sample program calls ASP.NET Web API methods which in turn call Task.Delay to simulate long-running web service calls. Most production applications will not show such obvious benefits to using asynchronous action methods.

Few applications require all action methods to be asynchronous. Often, converting a few synchronous action methods to asynchronous methods provides the best efficiency increase for the amount of work required.

The Sample Application

You can download the sample application from https://github.com/RickAndMSFT/Async-ASP.NET/ on the GitHub site. The repository consists of three projects:

- *Mvc4Async*: The ASP.NET MVC 4 project that contains the code used in this tutorial. It makes Web API calls to the **WebAPIpgw** service.
- *WebAPIpgw*: The ASP.NET MVC 4 Web API project that implements the `Products, Gizmos and Widgets` controllers. It provides the data for the *WebAppAsync* project and the *Mvc4Async* project.
- *WebAppAsync*: The ASP.NET Web Forms project used in another tutorial.

The Gizmos Synchronous Action Method

The following code shows the `Gizmos` synchronous action method that is used to display a list of gizmos. (For this article, a gizmo is a fictional mechanical device.)

```
public ActionResult Gizmos()
{
    ViewBag.SyncOrAsync = "Synchronous";
    var gizmoService = new GizmoService();
    return View("Gizmos", gizmoService.GetGizmos());
}
```

The following code shows the `GetGizmos` method of the gizmo service.

```
public class GizmoService
{
    public async Task<List<Gizmo>> GetGizmosAsync(
        // Implementation removed.

    public List<Gizmo> GetGizmos()
    {
        var uri = Util.getServiceUri("Gizmos");
        using (WebClient webClient = new WebClient())
        {
            return JsonConvert.DeserializeObject<List<Gizmo>>(
                webClient.DownloadString(uri)
            );
        }
    }
}
```

The `GizmoService GetGizmos` method passes a URI to an ASP.NET Web API HTTP service which returns a list of gizmos data. The *WebAPIpgw* project contains the implementation of the Web API `gizmos, widget` and `product` controllers.
The following image shows the gizmos view from the sample project.

Creating an Asynchronous Gizmos Action Method

The sample uses the new async and await keywords (available in .NET 4.5 and Visual Studio 2012) to let the compiler be responsible for maintaining the complicated transformations necessary for asynchronous programming. The compiler lets you write code using the C#'s synchronous control flow constructs and the compiler automatically applies the transformations necessary to use callbacks in order to avoid blocking threads.

The following code shows the `Gizmos` synchronous method and the `GizmosAsync` asynchronous method. If your browser supports the HTML 5 `<mark>` element, you'll see the changes in `GizmosAsync` in yellow highlight.

```
public ActionResult Gizmos()
{
    ViewBag.SyncOrAsync = "Synchronous";
    var gizmoService = new GizmoService();
    return View("Gizmos", gizmoService.GetGizmos());
}
```

```
public async Task<ActionResult> GizmosAsync()
{
    ViewBag.SyncOrAsync = "Asynchronous";
    var gizmoService = new GizmoService();
    return View("Gizmos", await gizmoService.GetGizmosAsync());
}
```

The following changes were applied to allow the `GizmosAsync` to be asynchronous.

- The method is marked with the async keyword, which tells the compiler to generate callbacks for parts of the body and to automatically create a `Task<ActionResult>` that is returned.
- "Async" was appended to the method name. Appending "Async" is not required but is the convention when writing asynchronous methods.
- The return type was changed from `ActionResult` to `Task<ActionResult>`. The return type of `Task<ActionResult>` represents ongoing work and provides callers of the method with a handle through which to wait for the asynchronous operation's completion. In this case, the caller is the web service. `Task<ActionResult>` represents ongoing work with a result of `ActionResult.`
- The await keyword was applied to the web service call.
- The asynchronous web service API was called (`GetGizmosAsync`).

Inside of the `GetGizmosAsync` method body another asynchronous method, `GetGizmosAsync` is called. `GetGizmosAsync` immediately returns a `Task<List<Gizmo>>` that will eventually complete when the data is available.

Because you don't want to do anything else until you have the gizmo data, the code awaits the task (using the **await** keyword). You can use the **await** keyword only in methods annotated with the **async** keyword.

The **await** keyword does not block the thread until the task is complete. It signs up the rest of the method as a callback on the task, and immediately returns. When the awaited task eventually completes, it will invoke that callback and thus resume the execution of the method right where it left off. For more information on using the await and async keywords and the Task namespace, see the async references.

The following code shows the `GetGizmos` and `GetGizmosAsync` methods.

```
public List<Gizmo> GetGizmos()
{
    var uri = Util.getServiceUri("Gizmos");
    using (WebClient webClient = new WebClient())
    {
        return JsonConvert.DeserializeObject<List<Gizmo>>(
            webClient.DownloadString(uri)
        );
    }
}
```

```
public async Task<List<Gizmo>> GetGizmosAsync()
{
    var uri = Util.getServiceUri("Gizmos");
    using (HttpClient httpClient = new HttpClient())
    {
        var response = await httpClient.GetAsync(uri);
        return (await response.Content.ReadAsAsync<List<Gizmo>>());
    }
}
```

The asynchronous changes are similar to those made to the **GizmosAsync** above.

- The method signature was annotated with the async keyword, the return type was changed to `Task<List<Gizmo>>`, and *Async* was appended to the method name.
- The asynchronous HttpClient class is used instead of the WebClient class.
- The await keyword was applied to the HttpClient asynchronous methods.

The following image shows the asynchronous gizmo view.

The browsers presentation of the gizmos data is identical to the view created by the synchronous call. The only difference is the asynchronous version may be more performant under heavy loads.

Performing Multiple Operations in Parallel

Asynchronous action methods have a significant advantage over synchronous methods when an action must perform several independent operations. In the sample provided, the synchronous method `PWG` (for Products, Widgets and Gizmos) displays the results of three web service calls to get a list of products, widgets, and gizmos. The ASP.NET Web API project that provides these services uses Task.Delay to simulate latency or slow network calls. When the delay is set to 500 milliseconds, the asynchronous `PWGasync` method takes a little over 500 milliseconds to complete while the synchronous `PWG` version takes over 1,500 milliseconds. The synchronous `PWG` method is shown in the following code.

```
public ActionResult PWG()
{
    ViewBag.SyncType = "Synchronous";
    var widgetService = new WidgetService();
    var prodService = new ProductService();
    var gizmoService = new GizmoService();

    var pwgVM = new ProdGizWidgetVM(
        widgetService.GetWidgets(),
        prodService.GetProducts(),
        gizmoService.GetGizmos()
       );

    return View("PWG", pwgVM);
}
```

The asynchronous `PWGasync` method is shown in the following code.

```
public async Task<ActionResult> PWGasync()
{
    ViewBag.SyncType = "Asynchronous";
    var widgetService = new WidgetService();
    var prodService = new ProductService();
    var gizmoService = new GizmoService();

    var widgetTask = widgetService.GetWidgetsAsync();
    var prodTask = prodService.GetProductsAsync();
    var gizmoTask = gizmoService.GetGizmosAsync();

    await Task.WhenAll(widgetTask, prodTask, gizmoTask);

    var pwgVM = new ProdGizWidgetVM(
       widgetTask.Result,
       prodTask.Result,
       gizmoTask.Result
       );

    return View("PWG", pwgVM);
}
```

The following image shows the view returned from the **PWGasync** method.

Using a Cancellation Token

Asynchronous action methods returning `Task<ActionResult>` are cancelable, that is they take a CancellationToken parameter when one is provided with the AsyncTimeout attribute. The following code shows the `GizmosCancelAsync` method with a timeout of 150 milliseconds.

```
[AsyncTimeout(150)]
[HandleError(ExceptionType = typeof(TimeoutException),
                                    View = "TimeoutError")]
public async Task<ActionResult> GizmosCancelAsync(
                        CancellationToken cancellationToken )
{
    ViewBag.SyncOrAsync = "Asynchronous";
    var gizmoService = new GizmoService();
    return View("Gizmos",
        await gizmoService.GetGizmosAsync(cancellationToken));
}
```

The following code shows the GetGizmosAsync overload, which takes a CancellationToken parameter.

```
public async Task<List<Gizmo>> GetGizmosAsync(string uri,
    CancellationToken cancelToken = default(CancellationToken))
{
    using (HttpClient httpClient = new HttpClient())
    {
        var response = await httpClient.GetAsync(uri, cancelToken);
        return (await response.Content.ReadAsAsync<List<Gizmo>>());
    }
}
```

In the sample application provided, selecting the *Cancellation Token Demo* link calls the `GizmosCancelAsync` method and demonstrates the cancellation of the asynchronous call.

Server Configuration for High Concurrency/High Latency Web Service Calls

To realize the benefits of an asynchronous web application, you might need to make some changes to the default server configuration. Keep the following in mind when configuring and stress testing your asynchronous web application.

- Windows 7, Windows Vista and all Windows client operating systems have a maximum of 10 concurrent requests. You'll need a Windows Server operating system to see the benefits of asynchronous methods under high load.
- Register .NET 4.5 with IIS from an elevated command prompt:
  %windir%\Microsoft.NET\Framework64\v4.0.30319\aspnet_regiis -i
  See ASP.NET IIS Registration Tool (Aspnet_regiis.exe)
- You might need to increase the HTTP.sys queue limit from the default value of 1,000 to 5,000. If the setting is too low, you may see HTTP.sys reject requests with a HTTP 503 status. To change the HTTP.sys queue limit:
  - Open IIS manager and navigate to the Application Pools pane.
  - Right click on the target application pool and select **Advanced Settings**.

- In the **Advanced Settings** dialog box, change *Queue Length* from 1,000 to 5,000.

Note in the images above, the .NET framework is listed as v4.0, even though the application pool is using .NET 4.5. To understand this discrepancy, see the following:

- .NET Versioning and Multi-Targeting - .NET 4.5 is an in-place upgrade to .NET 4.0
- How to set an IIS Application or AppPool to use ASP.NET 3.5 rather than 2.0

  - .NET Framework Versions and Dependencies
- If your application is using web services or System.NET to communicate with a backend over HTTP you may need to increase the connectionManagement/maxconnection element. For ASP.NET applications, this is limited by the autoConfig feature to 12 times the number of CPUs. That means that on a quad-proc, you can have at most 12 * 4 = 48 concurrent connections to an IP end point. Because this is tied to autoConfig, the easiest way to increase `maxconnection` in an ASP.NET application is to set System.Net.ServicePointManager.DefaultConnectionLimit programmatically in the from `Application_Start` method in the *global.asax* file. See the sample download for an example.
- In .NET 4.5, the default of 5000 for MaxConcurrentRequestsPerCPU should be fine.

Bundling and Minification

2/20/2020 • 13 minutes to read • Edit Online

by Rick Anderson

> Bundling and minification are two techniques you can use in ASP.NET 4.5 to improve request load time. Bundling and minification improves load time by reducing the number of requests to the server and reducing the size of requested assets (such as CSS and JavaScript.)

Most of the current major browsers limit the number of simultaneous connections per each hostname to six. That means that while six requests are being processed, additional requests for assets on a host will be queued by the browser. In the image below, the IE F12 developer tools network tabs shows the timing for assets required by the About view of a sample application.

The gray bars show the time the request is queued by the browser waiting on the six connection limit. The yellow bar is the request time to first byte, that is, the time taken to send the request and receive the first response from the server. The blue bars show the time taken to receive the response data from the server. You can double-click on an asset to get detailed timing information. For example, the following image shows the timing details for loading

the */Scripts/MyScripts/JavaScript6.js* file.

The preceding image shows the **Start** event, which gives the time the request was queued because of the browser limit the number of simultaneous connections. In this case, the request was queued for 46 milliseconds waiting for another request to complete.

Bundling

Bundling is a new feature in ASP.NET 4.5 that makes it easy to combine or bundle multiple files into a single file. You can create CSS, JavaScript and other bundles. Fewer files means fewer HTTP requests and that can improve first page load performance.

The following image shows the same timing view of the About view shown previously, but this time with bundling and minification enabled.

Minification

Minification performs a variety of different code optimizations to scripts or css, such as removing unnecessary white space and comments and shortening variable names to one character. Consider the following JavaScript function.

```
AddAltToImg = function (imageTagAndImageID, imageContext) {
    ///<signature>
    ///<summary> Adds an alt tab to the image
    // </summary>
    //<param name="imgElement" type="String">The image selector.</param>
    //<param name="ContextForImage" type="String">The image context.</param>
    ///</signature>
    var imageElement = $(imageTagAndImageID, imageContext);
    imageElement.attr('alt', imageElement.attr('id').replace(/ID/, ''));
}
```

After minification, the function is reduced to the following:

```
AddAltToImg = function (n, t) { var i = $(n, t); i.attr("alt", i.attr("id").replace(/ID/, "")) }
```

In addition to removing the comments and unnecessary whitespace, the following parameters and variable names were renamed (shortened) as follows:

ORIGINAL	RENAMED
imageTagAndImageID	n
imageContext	t
imageElement	i

Impact of Bundling and Minification

The following table shows several important differences between listing all the assets individually and using bundling and minification (B/M) in the sample program.

	USING B/M	WITHOUT B/M	CHANGE
File Requests	9	34	256%
KB Sent	3.26	11.92	266%
KB Received	388.51	530	36%
Load Time	510 MS	780 MS	53%

The bytes sent had a significant reduction with bundling as browsers are fairly verbose with the HTTP headers they apply on requests. The received bytes reduction is not as large because the largest files (*Scripts\jquery-ui-1.8.11.min.js* and *Scripts\jquery-1.7.1.min.js*) are already minified. Note: The timings on the sample program used the Fiddler tool to simulate a slow network. (From the Fiddler **Rules** menu, select **Performance** then **Simulate Modem Speeds**.)

Debugging Bundled and Minified JavaScript

It's easy to debug your JavaScript in a development environment (where the compilation Element in the *Web.config* file is set to `debug="true"`) because the JavaScript files are not bundled or minified. You can also debug a release build where your JavaScript files are bundled and minified. Using the IE F12 developer tools, you debug a JavaScript function included in a minified bundle using the following approach:

1. Select the **Script** tab and then select the **Start debugging** button.
2. Select the bundle containing the JavaScript function you want to debug using the assets button.

3. Format the minified JavaScript by selecting the **Configuration button** , and then selecting **Format JavaScript**.
4. In the **Search Script** input box, select the name of the function you want to debug. In the following image, **AddAltToImg** was entered in the **Search Script** input box.

For more information on debugging with the F12 developer tools, see the MSDN article Using the F12 Developer Tools to Debug JavaScript Errors.

Controlling Bundling and Minification

Bundling and minification is enabled or disabled by setting the value of the debug attribute in the compilation Element in the *Web.config* file. In the following XML, `debug` is set to true so bundling and minification is disabled.

```
<system.web>
    <compilation debug="true" />
    <!-- Lines removed for clarity. -->
</system.web>
```

To enable bundling and minification, set the `debug` value to "false". You can override the *Web.config* setting with the `EnableOptimizations` property on the `BundleTable` class. The following code enables bundling and minification and overrides any setting in the *Web.config* file.

```
public static void RegisterBundles(BundleCollection bundles)
{
    bundles.Add(new ScriptBundle("~/bundles/jquery").Include(
                "~/Scripts/jquery-{version}.js"));

    // Code removed for clarity.
    BundleTable.EnableOptimizations = true;
}
```

NOTE

Unless `EnableOptimizations` is `true` or the debug attribute in the compilation Element in the *Web.config* file is set to `false`, files will not be bundled or minified. Additionally, the .min version of files will not be used, the full debug versions will be selected. `EnableOptimizations` overrides the debug attribute in the compilation Element in the *Web.config* file

Using Bundling and Minification with ASP.NET Web Forms and Web Pages

- For Web Pages, see the blog entry Adding Web Optimization to a Web Pages Site.
- For Web Forms, see the blog entry Adding Bundling and Minification to Web Forms.

Using Bundling and Minification with ASP.NET MVC

In this section we will create an ASP.NET MVC project to examine bundling and minification. First, create a new ASP.NET MVC internet project named **MvcBM** without changing any of the defaults.

Open the *App_Start\BundleConfig.cs* file and examine the `RegisterBundles` method which is used to create, register and configure bundles. The following code shows a portion of the `RegisterBundles` method.

```
public static void RegisterBundles(BundleCollection bundles)
{
     bundles.Add(new ScriptBundle("~/bundles/jquery").Include(
                 "~/Scripts/jquery-{version}.js"));
         // Code removed for clarity.
}
```

The preceding code creates a new JavaScript bundle named *~/bundles/jquery* that includes all the appropriate (that is debug or minified but not *.vsdoc*) files in the *Scripts* folder that match the wild card string "~/Scripts/jquery-{version}.js". For ASP.NET MVC 4, this means with a debug configuration, the file *jquery-1.7.1.js* will be added to the bundle. In a release configuration, *jquery-1.7.1.min.js* will be added. The bundling framework

follows several common conventions such as:

- Selecting ".min" file for release when *FileX.min.js* and *FileX.js* exist.
- Selecting the non ".min" version for debug.
- Ignoring "-vsdoc" files (such as *jquery-1.7.1-vsdoc.js*), which are used only by IntelliSense.

The `{version}` wild card matching shown above is used to automatically create a jQuery bundle with the appropriate version of jQuery in your *Scripts* folder. In this example, using a wild card provides the following benefits:

- Allows you to use NuGet to update to a newer jQuery version without changing the preceding bundling code or jQuery references in your view pages.
- Automatically selects the full version for debug configurations and the ".min" version for release builds.

Using a CDN

The follow code replaces the local jQuery bundle with a CDN jQuery bundle.

```
public static void RegisterBundles(BundleCollection bundles)
{
    //bundles.Add(new ScriptBundle("~/bundles/jquery").Include(
    //            "~/Scripts/jquery-{version}.js"));

    bundles.UseCdn = true;   //enable CDN support

    //add link to jquery on the CDN
    var jqueryCdnPath = "https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.7.1.min.js";

    bundles.Add(new ScriptBundle("~/bundles/jquery",
                jqueryCdnPath).Include(
                "~/Scripts/jquery-{version}.js"));

    // Code removed for clarity.
}
```

In the code above, jQuery will be requested from the CDN while in release mode and the debug version of jQuery will be fetched locally in debug mode. When using a CDN, you should have a fallback mechanism in case the CDN request fails. The following markup fragment from the end of the layout file shows script added to request jQuery should the CDN fail.

```
</footer>

        @Scripts.Render("~/bundles/jquery")

        <script type="text/javascript">
            if (typeof jQuery == 'undefined') {
                var e = document.createElement('script');
                e.src = '@Url.Content("~/Scripts/jquery-1.7.1.js")';
                e.type = 'text/javascript';
                document.getElementsByTagName("head")[0].appendChild(e);

            }
        </script>

        @RenderSection("scripts", required: false)
    </body>
</html>
```

Creating a Bundle

The Bundle class `Include` method takes an array of strings, where each string is a virtual path to resource. The following code from the `RegisterBundles` method in the *App_Start\BundleConfig.cs* file shows how multiple files are added to a bundle:

```
bundles.Add(new StyleBundle("~/Content/themes/base/css").Include(
    "~/Content/themes/base/jquery.ui.core.css",
    "~/Content/themes/base/jquery.ui.resizable.css",
    "~/Content/themes/base/jquery.ui.selectable.css",
    "~/Content/themes/base/jquery.ui.accordion.css",
    "~/Content/themes/base/jquery.ui.autocomplete.css",
    "~/Content/themes/base/jquery.ui.button.css",
    "~/Content/themes/base/jquery.ui.dialog.css",
    "~/Content/themes/base/jquery.ui.slider.css",
    "~/Content/themes/base/jquery.ui.tabs.css",
    "~/Content/themes/base/jquery.ui.datepicker.css",
    "~/Content/themes/base/jquery.ui.progressbar.css",
    "~/Content/themes/base/jquery.ui.theme.css"));
```

The Bundle class `IncludeDirectory` method is provided to add all the files in a directory (and optionally all subdirectories) which match a search pattern. The Bundle class `IncludeDirectory` API is shown below:

```
public Bundle IncludeDirectory(
    string directoryVirtualPath,  // The Virtual Path for the directory.
    string searchPattern)         // The search pattern.

public Bundle IncludeDirectory(
    string directoryVirtualPath,  // The Virtual Path for the directory.
    string searchPattern,         // The search pattern.
    bool searchSubdirectories)    // true to search subdirectories.
```

Bundles are referenced in views using the Render method, (`Styles.Render` for CSS and `Scripts.Render` for JavaScript). The following markup from the *Views\Shared_Layout.cshtml* file shows how the default ASP.NET internet project views reference CSS and JavaScript bundles.

```
<!DOCTYPE html>
<html lang="en">
<head>
    @* Markup removed for clarity.*@
    @Styles.Render("~/Content/themes/base/css", "~/Content/css")
    @Scripts.Render("~/bundles/modernizr")
</head>
<body>
    @* Markup removed for clarity.*@

   @Scripts.Render("~/bundles/jquery")
   @RenderSection("scripts", required: false)
</body>
</html>
```

Notice the Render methods takes an array of strings, so you can add multiple bundles in one line of code. You will generally want to use the Render methods which create the necessary HTML to reference the asset. You can use the `Url` method to generate the URL to the asset without the markup needed to reference the asset. Suppose you wanted to use the new HTML5 async attribute. The following code shows how to reference modernizr using the `Url` method.

```
<head>
    @*Markup removed for clarity*@
    <meta charset="utf-8" />
    <title>@ViewBag.Title - MVC 4 B/M</title>
    <link href="~/favicon.ico" rel="shortcut icon" type="image/x-icon" />
    <meta name="viewport" content="width=device-width" />
    @Styles.Render("~/Content/css")

   @* @Scripts.Render("~/bundles/modernizr")*@

    <script src='@Scripts.Url("~/bundles/modernizr")' async> </script>
</head>
```

Using the "*" Wildcard Character to Select Files

The virtual path specified in the `Include` method and the search pattern in the `IncludeDirectory` method can accept one "*" wildcard character as a prefix or suffix to in the last path segment. The search string is case insensitive. The `IncludeDirectory` method has the option of searching subdirectories.

Consider a project with the following JavaScript files:

- *Scripts\Common\AddAltToImg.js*
- *Scripts\Common\ToggleDiv.js*
- *Scripts\Common\ToggleImg.js*
- *Scripts\Common\Sub1\ToggleLinks.js*

The following table shows the files added to a bundle using the wildcard as shown:

CALL	FILES ADDED OR EXCEPTION RAISED
Include("~/Scripts/Common/*.js")	*AddAltToImg.js*, *ToggleDiv.js*, *ToggleImg.js*
Include("~/Scripts/Common/T*.js")	Invalid pattern exception. The wildcard character is only allowed on the prefix or suffix.
Include("~/Scripts/Common/*og.*")	Invalid pattern exception. Only one wildcard character is allowed.
Include("~/Scripts/Common/T*")	*ToggleDiv.js*, *ToggleImg.js*
Include("~/Scripts/Common/*")	Invalid pattern exception. A pure wildcard segment is not valid.
IncludeDirectory("~/Scripts/Common", "T*")	*ToggleDiv.js*, *ToggleImg.js*
IncludeDirectory("~/Scripts/Common", "T*", true)	*ToggleDiv.js*, *ToggleImg.js*, *ToggleLinks.js*

Explicitly adding each file to a bundle is generally the preferred over wildcard loading of files for the following reasons:

- Adding scripts by wildcard defaults to loading them in alphabetical order, which is typically not what you want. CSS and JavaScript files frequently need to be added in a specific (non-alphabetic) order. You can mitigate this risk by adding a custom IBundleOrderer implementation, but explicitly adding each file is less error prone. For example, you might add new assets to a folder in the future which might require you to modify your IBundleOrderer implementation.

- View specific files added to a directory using wild card loading can be included in all views referencing that bundle. If the view specific script is added to a bundle, you may get a JavaScript error on other views that reference the bundle.

- CSS files that import other files result in the imported files loaded twice. For example, the following code creates a bundle with most of the jQuery UI theme CSS files loaded twice.

  ```
  bundles.Add(new StyleBundle("~/jQueryUI/themes/baseAll")
      .IncludeDirectory("~/Content/themes/base", "*.css"));
  ```

  The wild card selector "*.css" brings in each CSS file in the folder, including the *Content\themes\base\jquery.ui.all.css* file. The *jquery.ui.all.css* file imports other CSS files.

Bundle Caching

Bundles set the HTTP Expires Header one year from when the bundle is created. If you navigate to a previously viewed page, Fiddler shows IE does not make a conditional request for the bundle, that is, there are no HTTP GET requests from IE for the bundles and no HTTP 304 responses from the server. You can force IE to make a conditional request for each bundle with the F5 key (resulting in a HTTP 304 response for each bundle). You can force a full refresh by using ^F5 (resulting in a HTTP 200 response for each bundle.)

The following image shows the **Caching** tab of the Fiddler response pane:

The request

`http://localhost/MvcBM_time/bundles/AllMyScripts?v=r0sLDicvP58AIXN_mc3QdyVvVj5euZNzdsa2N1PKvb81`

is for the bundle **AllMyScripts** and contains a query string pair **v=r0sLDicvP58AIXN_mc3QdyVvVj5euZNzdsa2N1PKvb81**. The query string **v** has a value token that is a unique identifier used for caching. As long as the bundle doesn't change, the ASP.NET application will request the **AllMyScripts** bundle using this token. If any file in the bundle changes, the ASP.NET optimization framework will generate a new token, guaranteeing that browser requests for the bundle will get the latest bundle.

If you run the IE9 F12 developer tools and navigate to a previously loaded page, IE incorrectly shows conditional GET requests made to each bundle and the server returning HTTP 304. You can read why IE9 has problems determining if a conditional request was made in the blog entry Using CDNs and Expires to Improve Web Site Performance.

LESS, CoffeeScript, SCSS, Sass Bundling.

The bundling and minification framework provides a mechanism to process intermediate languages such as SCSS, Sass, LESS or Coffeescript, and apply transforms such as minification to the resulting bundle. For example, to add

.less files to your MVC 4 project:

1. Create a folder for your LESS content. The following example uses the *Content\MyLess* folder.

2. Add the .less NuGet package **dotless** to your project.

3. Add a class that implements the IBundleTransform interface. For the .less transform, add the following code to your project.

```
using System.Web.Optimization;

public class LessTransform : IBundleTransform
{
    public void Process(BundleContext context, BundleResponse response)
    {
        response.Content = dotless.Core.Less.Parse(response.Content);
        response.ContentType = "text/css";
    }
}
```

4. Create a bundle of LESS files with the `LessTransform` and the CssMinify transform. Add the following code to the `RegisterBundles` method in the *App_Start\BundleConfig.cs* file.

```
var lessBundle = new Bundle("~/My/Less").IncludeDirectory("~/My", "*.less");
lessBundle.Transforms.Add(new LessTransform());
lessBundle.Transforms.Add(new CssMinify());
bundles.Add(lessBundle);
```

5. Add the following code to any views which references the LESS bundle.

```
@Styles.Render("~/My/Less");
```

Bundle Considerations

A good convention to follow when creating bundles is to include "bundle" as a prefix in the bundle name. This will prevent a possible routing conflict.

Once you update one file in a bundle, a new token is generated for the bundle query string parameter and the full bundle must be downloaded the next time a client requests a page containing the bundle. In traditional markup where each asset is listed individually, only the changed file would be downloaded. Assets that change frequently may not be good candidates for bundling.

Bundling and minification primarily improve the first page request load time. Once a webpage has been requested, the browser caches the assets (JavaScript, CSS and images) so bundling and minification won't provide any performance boost when requesting the same page, or pages on the same site requesting the same assets. If you don't set the expires header correctly on your assets, and you don't use bundling and minification, the browsers freshness heuristics will mark the assets stale after a few days and the browser will require a validation request for each asset. In this case, bundling and minification provide a performance increase after the first page request. For details, see the blog Using CDNs and Expires to Improve Web Site Performance.

The browser limitation of six simultaneous connections per each hostname can be mitigated by using a CDN. Because the CDN will have a different hostname than your hosting site, asset requests from the CDN will not count against the six simultaneous connections limit to your hosting environment. A CDN can also provide common package caching and edge caching advantages.

Bundles should be partitioned by pages that need them. For example, the default ASP.NET MVC template for an internet application creates a jQuery Validation bundle separate from jQuery. Because the default views created have no input and do not post values, they don't include the validation bundle.

The `System.Web.Optimization` namespace is implemented in *System.Web.Optimization.dll*. It leverages the WebGrease library (*WebGrease.dll*) for minification capabilities, which in turn uses *Antlr3.Runtime.dll*.

Advanced topics for programming ASP.NET MVC, including accessibility, extensibility, and internationalization.

- Custom MVC Template

Custom MVC Template

2/20/2020 • 6 minutes to read • Edit Online

by Jacques Eloff

The release of MVC 3 Tools Update for Visual Studio 2010 introduced a separate project wizard for MVC projects. The change was driven by two factors. First, the introduction of new templates in MVC 3 and support for additional view engines such as Razor lead to overcrowding the New Project dialog in Visual Studio. Second, customers had been asking for extensibility points and the new MVC project wizard would afford us the opportunity to respond to these requests.

Adding custom templates was an arduous process that relied on using the registry to make new templates visible to the MVC project wizard. The author of a new template had to wrap it inside an MSI to ensure that the necessary registry entries would be created at install time. The alternative was to make a ZIP file containing the template available and have the end-user create the required registry entries by hand.

Neither of the aforementioned approaches is ideal so we decided to leverage some of the existing infrastructure provided by VSIX extensions to make it easier to author, distribute and install custom MVC templates starting with MVC 4 for Visual Studio 2012. Some of the benefits provided by this approach are:

- A VSIX extension can contain multiple templates that support different languages (C# and Visual Basic) and multiple view engines (ASPX and Razor).
- A VSIX extension can target multiple SKUs of Visual Studio including Express SKUs.
- The Visual Studio Gallery facilitates distributing the extension to a wide audience.
- VSIX extensions can be upgraded making it easier to author corrections and updates to your custom templates.

Prerequisites

- Users need to be familiar with authoring project templates, including the required markup for vstemplate files, etc.
- Users will need to have Visual Studio Professional and higher installed. Express SKUs do not support creating VSIX projects.
- Visual Studio 2012 SDK installed.

Example

The first step is to create a new VSIX project using either C# or Visual Basic. Select **File > New Project**, then click **Extensibility** in the left pane and select the **VSIX Project**.

After the project is created, the VSIX designer will be opened.

The designer can be used to edit some of the general properties of the extension that will be shown to users when they install the extension or browse the installed extensions in Visual Studio (**Tools > Extensions and Updates**). Once you have completed the general information click on the **Install Targets tab**.

This tab is used to specify the SKUs and versions of Visual Studio that are supported by your extension. Select the checkbox for **This VSIX is installed for all users** to enable per-machine installs of the VSIX. Click on the **New** button on the right to add additional SKUs such as Web Developer Express (VWD).

If you intend to support all the Professional and higher SKUs (Professional, Premium and Ultimate) you only need to select the minimum SKU in the family, **Microsoft.VisualStudio.Pro**. Remember to save all your changes once you have completed the Install Targets.

The **Assets** tab is used to add all your content files to the VSIX. Since MVC requires custom metadata you will be editing the raw XML of the VSIX manifest file instead of using the **Assets** tab to add content. Start by adding the template contents to the VSIX project. It is important that the structure of the folder and the contents mirror the layout of the project. The example below contains four project templates that were derived from the Basic MVC project template. Make sure that all the files that comprise your project template (everything underneath the ProjectTemplates folder) are added to the **Content** itemgroup in the VSIX project file and that each item contains the **CopyToOutputDirectory** and **IncludeInVsix** metadata set as shown in the example below.

```
<Content Include="ProjectTemplates\MyMvcWebApplicationProjectTemplate.csaspx\BasicWeb.config">

<CopyToOutputDirectory>Always</CopyToOutputDirectory>

<IncludeInVSIX>true</IncludeInVSIX>

</Content>
```

If not, the IDE will try to compile the contents of the template when you build the VSIX and you will likely see an error. Code files in templates often contain special template parameters used by Visual Studio when the project template is instantiated and therefore cannot be compiled in the IDE.

Close the VSIX designer, then right click on the **source.extension.manifest** file in **Solution Explorer** and select **Open With** and choose the **XML (Text) Editor** option.

Create an **<Assets>** element and add an **<Asset>** element for each file that must be included in the VSIX. The **Type** attribute of each **<Asset>** element must be set to **Microsoft.VisualStudio.Mvc.Template**. This is a custom namespace that only the MVC project wizard understands. Refer to the VSIX 2.0 Schema documentation for additional information on the structure and layout of the manifest file.

Just adding the files to the VSIX is not sufficient to register the templates with the MVC wizard. You need to provide information such as the template name, description, supported view engines and programming language to the MVC wizard. This information is carried in custom attributes associated with the **<Asset>** element for each **vstemplate** file.

<Asset d:VsixSubPath="ProjectTemplates\MyMvcWebApplicationProjectTemplate.csaspx"

Type="Microsoft.VisualStudio.Mvc.Template"

d:Source="File"

Path="ProjectTemplates\MyMvcWebApplicationProjectTemplate.csaspx\BasicMvcWebApplicationProjectTemplate.11.csaspx.vstemplate"

ProjectType="MVC"

Language="C#"

ViewEngine="Aspx"

TemplateId="MyMvcApplication"

Title="Custom Basic Web Application"

Description="A custom template derived from a Basic MVC web application (Razor)"

Version="4.0"/>

Below is an explanation of the custom attributes that must be present:

- **ProjectType** must be set to MVC.
- **Language** designates the development language supported by the template. Valid values are either C# or VB.
- **ViewEngine** designates the view engine supported by the template such as Aspx or Razor. You can specify a custom value for this field.
- **TemplateId** is used for grouping the templates. If the value matches an existing template ID it will be override templates previously registered with the MVC wizard.
- **Title** designates the short description displayed in the MVC wizard beneath each project template.
- **Description** designates a more verbose description of the template.

After you have added all the files to the manifest and saved it, you will notice that the **Assets** tab in the designer will display all the files, but not the custom attributes you added to the **<Asset>** elements for the **vstemplate** files.

All that remains now is to compile the VSIX project and install it.

Make sure that all instances of Visual Studio are closed on the machine where you intend to test the VSIX extension. Visual Studio scans for new extensions during startup, so if the IDE is open while installing a VSIX you will need to restart Visual Studio. In Explorer, double click on the VSIX file to launch the **VSIX Installer**, click **Install** and then launch Visual Studio.

From the menu, select **Tools > Extensions and Updates** to confirm that your extension was installed. If the VSIX Installer reported any errors during the installation of the extension you can view the VSIX Installer log for more information. The log is usually created in the **%temp%** folder of the user that installed the extension, for example **C:\Users\Bob\AppData\Local\Temp**.

After closing the window you can create an MVC 4 project to see whether your new templates are shown in the MVC wizard.

Limitations

1. The MVC wizard does not support localized custom templates.
2. The wizard will not report any errors if it fails to locate custom templates. If any of the required custom attributes are absent, the template would simply be excluded from the Wizard.

Releases

2/20/2020 • 2 minutes to read • Edit Online

What's new in recent MVC releases.

- What’s New in ASP.NET MVC 5.2
- What's New in ASP.NET MVC 5.1
- How to Upgrade an ASP.NET MVC 4 and Web API Project to ASP.NET MVC 5 and Web API 2

What's New in ASP.NET MVC 5.2

4/10/2020 • 5 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET MVC 5.2, Microsoft.AspNet.MVC 5.2.2 and ASP.NET MVC 5.2.3 Beta

- Software Requirements
- Download
- Documentation
- New Features in ASP.NET MVC 5.2
  - Attribute routing improvements
- Known Issues and Breaking Changes
- Bug Fixes
- Microsoft.AspNet.MVC 5.2.2

Software Requirements

- Visual Studio 2012: Download ASP.NET and Web Tools 2013.1 for Visual Studio 2012.
- Visual Studio 2013: Download Visual Studio 2013 Update or higher. This update is needed for editing ASP.NET MVC 5.2 Razor Views.

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The latest ASP.NET MVC 5.2 package has the following version: "5.2.0". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

Install-Package Microsoft.AspNet.Mvc -Version 5.2.0

Documentation

Tutorials and other information about ASP.NET MVC 5.2 are available from the ASP.NET web site (https://www.asp.net/mvc).

New Features in ASP.NET MVC 5.2

Attribute routing improvements

Attribute Routing now provides an extensibility point called IDirectRouteProvider, which allows full control over how attribute routes are discovered and configured. An IDirectRouteProvider is responsible for providing a list of actions and controllers along with associated route information to specify exactly what routing configuration is desired for those actions. An IDirectRouteProvider implementation may be specified when calling MapAttributes/MapHttpAttributeRoutes.

Customizing IDirectRouteProvider will be easiest by extending our default implementation, DefaultDirectRouteProvider. This class provides separate overridable virtual methods to change the logic for discovering attributes, creating route entries, and discovering route prefix and area prefix.

With the new attribute routing extensibility of IDirectRouteProvider, a user could do the following:

1. Support Inheritance of attribute routes. For example, in the following scenario Blog and Store controllers are using an attribute route convention that is defined by the BaseController.

```
[InheritedRoute("attributerouting/{controller}/{action=Index}/{id?}")]
public abstract class BaseController : Controller
{
}
public class BlogController : BaseController
{
    public string Index()
    {
        return "Hello from blog!";
    }
}
public class StoreController : BaseController
{
    public string Index()
    {
        return "Hello from store!";
    }
}
[AttributeUsage(AttributeTargets.Class, Inherited=true, AllowMultiple=true)]
public class InheritedRouteAttribute : Attribute, IDirectRouteFactory
{
    public InheritedRouteAttribute(string template)
    {
        Template=template;
    }
    public string Name { get; set; }
    public int Order { get; set; }
    public string Template { get; private set; }
    public new RouteEntry CreateRoute(DirectRouteFactoryContext context)
    {
        // context.Actions will always contain at least one action - and all of the
        // actions will always belong to the same controller.
        var controllerDescriptor=context.Actions.First().ControllerDescriptor;
        var template=Template.Replace("{controller}",
            controllerDescriptor.ControllerName);
        IDirectRouteBuilder builder=context.CreateBuilder(template);
        builder.Name=Name;
        builder.Order=Order;
        return builder.Build();
    }
}
// Custom direct route provider which looks for route attributes of type
// InheritedRouteAttribute and also supports attribute route inheritance.
public class InheritedDirectRouteProvider : DefaultDirectRouteProvider
{
    protected override IReadOnlyList<IDirectRouteFactory>
         GetControllerRouteFactories(ControllerDescriptor controllerDescriptor)
    {
        return controllerDescriptor
            .GetCustomAttributes(typeof(InheritedRouteAttribute), inherit: true)
            .Cast<IDirectRouteFactory>()
            .ToArray();
    }
}
```

2. Automatically generate route names for attribute routes.

```
protected override IReadOnlyList<IDirectRouteFactory>
         GetActionRouteFactories(ActionDescriptor actionDescriptor)
{
    // Get all the route attributes decorated directly on the actions
    IReadOnlyList<IDirectRouteFactory>
actionRouteFactories=base.GetActionRouteFactories(actionDescriptor);
    // Check if the route attribute on each action already has a route name and if no,
    // generate a route name automatically
    // based on the convention: <ControllerName>_<ActionName> (ex: Customers_GetById)
    foreach (IDirectRouteFactory routeFactory in actionRouteFactories)
    {
        RouteAttribute routeAttr=routeFactory as RouteAttribute;
        if (string.IsNullOrEmpty(routeAttr.Name))
        {
            routeAttr.Name=actionDescriptor.ControllerDescriptor.ControllerName + "_"
                  + actionDescriptor.ActionName;
        }
    }
    return actionRouteFactories;
}
protected override IReadOnlyList<IDirectRouteFactory>
      GetControllerRouteFactories(ControllerDescriptor controllerDescriptor)
{
    // Get all the route attributes decorated directly on the controllers
    IReadOnlyList<IDirectRouteFactory>
controllerRouteFactories=base.GetControllerRouteFactories(controllerDescriptor);
    // Check if the route attribute on each controller already has a route name and if no,
    // generate a route name automatically
    // based on the convention: <ControllerName>Route (ex: CustomersRoute)
    foreach (IDirectRouteFactory routeFactory in controllerRouteFactories)
    {
        RouteAttribute routeAttr=routeFactory as RouteAttribute;
        if (string.IsNullOrEmpty(routeAttr.Name))
        {
            routeAttr.Name=controllerDescriptor.ControllerName + "Route";
        }
    }
    return controllerRouteFactories;
}
```

3. Modify route prefixes in one central place before the routes get added to the route table.
4. Filter out the controllers on which you want the attribute routing to look for. We hope to blog on 3 and 4 soon.

Facebook fixes for changed API surface

The MVC Facebook package was broken due to few API changes made by Facebook. We are also releasing a new Facebook package (Microsoft.AspNet.Facebook 1.0.0) to fix these issues.

Known Issues and Breaking Changes

Scaffolding MVC/Web API into a project with 5.2.0 packages results in 5.1.2 packages for ones that don't already exist in the project

Updating NuGet packages for ASP.NET MVC 5.2.0 does not update the Visual Studio tools such as ASP.NET scaffolding or the ASP.NET Web Application project template. They use the previous version of the ASP.NET runtime packages (e.g. 5.1.2 in Update 2). As a result, the ASP.NET scaffolding will install the previous version (e.g. 5.1.2 in Update 2) of the required packages, if they are not already available in your projects. However, the ASP.NET scaffolding in Visual Studio 2013 RTM or Update 1 does not overwrite the latest packages in your projects. If you use ASP.NET scaffolding after updating the packages of your projects to Web API 2.2 or ASP.NET MVC 5.2, make sure the versions of Web API and ASP.NET MVC are consistent.

Microsoft.jQuery.Unobtrusive.Validation NuGet package installation fails because it is unable to find a version of Microsoft.jQuery.Unobtrusive.Validation compatible to jQuery 1.4.1

Microsoft.jQuery.Unobtrusive.Validation requires jQuery >=1.8 and jQuery.Validation >=1.8. But,jQuery.Validation (1.8) needs jQuery (≥ 1.3.2 && ≤ 1.6). Because of this, when NuGet installs the JQuery 1.8 and jQuery.Validation 1.8 at the same time, it fails. When you see this issue, you can simply update the version of jQuery.Validation to >= 1.8.0.1 which has the jQuery cap fixed first, you should be able to install Microsoft.jQuery.Unobtrusive.Validation.

The jquery.Validation nuget package version 1.13.0 does not recognize some international email addresses

jQuery.Validation nuget package version 1.11.1 is the last known version which recognizes following valid email addresses. Any later versions might not be able to recognize them. For example:

E-Mail Address Internationalization (EAI) standard (e.g., 用户@domain.com)
EAI + Internationalized Resource Identifiers (IRIs) (eg., 用户@домен.рф)

The issue is reported at https://github.com/jzaefferer/jquery-validation/issues/1222

Syntax Highlighting for Razor Views in Visual Studio 2013

If you update to ASP.NET MVC 5.2 without updating Visual Studio 2013, you will not get Visual Studio editor support for syntax highlighting while editing the Razor views. You will need to update Visual Studio 2013 to get this support.

Bug Fixes and Minor feature updates

This release also includes several bug fixes and minor feature updates. You can find the complete list here:

- 5.2 package

Microsoft.AspNet.MVC 5.2.2

This release doesn't have any new features or bug fixes in MVC. We made a change in Web Pages for a significant performance improvement and have subsequently updated all other dependent packages we own to depend on this new version of Web Pages.

ASP.NET MVC 5.2.3 Beta

You can read about the release here. This release contains only bug fixes. You can use this query to see the list of issues fixed in this release.

What's New in ASP.NET MVC 5.1

4/10/2020 • 3 minutes to read • Edit Online

by Microsoft

This topic describes what's new for ASP.NET Web MVC 5.1.

- Software Requirements
- Download
- Documentation
- New Features in ASP.NET MVC 5.1
  - Attribute routing improvements
  - Bootstrap support for editor templates
  - Enum support in views
  - Unobtrusive validation for MinLength/MaxLength Attributes
  - Supporting the 'this' context in Unobtrusive Ajax
- Known Issues and Breaking Changes- Bug Fixes

Software Requirements

- Visual Studio 2012: Download ASP.NET and Web Tools 2013.1 for Visual Studio 2012.
- Visual Studio 2013: Download Visual Studio 2013 Update 1. This update is needed for editing ASP.NET MVC 5.1 Razor Views.

Download

The runtime features are released as NuGet packages on the NuGet gallery. All the runtime packages follow the Semantic Versioning specification. The latest ASP.NET MVC 5.1 RTM package has the following version: "5.1.2". You can install or update these packages through NuGet. The release also includes corresponding localized packages on NuGet.

You can install or update to the released NuGet packages by using the NuGet Package Manager Console:

```
Install-Package Microsoft.AspNet.Mvc -Version 5.1.2
```

Documentation

Tutorials and other information about ASP.NET MVC 5.1 RTM are available from the ASP.NET web site (https://www.asp.net).

New Features in ASP.NET MVC 5.1

Attribute routing improvements

Attribute routing now supports constraints, enabling versioning and header based route selection. Many aspects of attribute routes are now customizable via the `IDirectRouteFactory` interface and `RouteFactoryAttribute` class. The route prefix is now extensible via the `IRoutePrefix` interface and `RoutePrefixAttribute` class.

Enum support in views

1. New `@Html.EnumDropDownListFor()` helper methods. These should be used like most of the HTML helpers with the caveat that the expression must evaluate to an enum type or a Nullable<T> where `T` is an enum type. Use `EnumHelper.IsValidForEnumHelper()` to check these requirements.
2. New `EnumHelper.GetSelectList()` methods which return an `IList<SelectListItem>`. This is useful when you need to manipulate a select list prior to calling, for example, `@Html.DropDownListFor()`, or when you wish to display the names which `@Html.EnumDropDownListFor()` shows.

The following code shows these APIs.

```
@if (EnumHelper.IsValidForEnumHelper(ViewData.ModelMetadata))
{
    @Html.EnumDropDownListFor(model => model, htmlAttributes: new { @class = "form-control" })
}
@if (EnumHelper.IsValidForEnumHelper(ViewData.ModelMetadata))
{
    foreach (SelectListItem item in EnumHelper.GetSelectList(ViewData.ModelMetadata,
(Enum)Model)) { … }
}
```

You can see a complete example here.

Bootstrap support for editor templates

We now allow passing in HTML attributes in EditorFor as an anonymous object.

For example:

```
@Html.EditorFor(model => model, new { htmlAttributes = new { @class = "form-control" }, })
```

Unobtrusive validation for MinLengthAttribute and MaxLengthAttribute

Client-side validation for string and array types will now be supported for properties decorated with the MinLength and MaxLength attributes.

Supporting the 'this' context in Unobtrusive Ajax

The callback functions (`OnBegin, OnComplete, OnFailure, OnSuccess`) will now be able to locate the invoking element via the `this` context. For example:

```
@Ajax.ActionLink("Click me", "AjaxAction", new AjaxOptions { UpdateTargetId = "foo", OnBegin = "OnClick" })

<script>
    function OnClick(jqXHR) {
        if ($(this).hasClass("foo")) {
            jqXHR.setRequestHeader("custom-header", "value");
        }
    }
</script>
```

Known Issues and Breaking Changes

Attribute Routing

Ambiguities in attribute routing matches will now report an error rather than choosing the first match.

Attribute routes are prohibited from using the `{controller}` parameter, and from using the `{action}` parameter on routes placed on actions. Uses of these parameters would very likely lead to ambiguities.

Scaffolding MVC/Web API into a project with 5.1 packages results in 5.0 packages for ones that don't already exist in the project

Updating NuGet packages for ASP.NET MVC 5.1 RTM does not update the Visual Studio tools such as ASP.NET scaffolding or the ASP.NET Web Application project template. They use the previous version of the ASP.NET runtime packages (5.0.0.0). As a result, the ASP.NET scaffolding will install the previous version (5.0.0.0) of the required packages, if they are not already available in your projects. However, the ASP.NET scaffolding in Visual Studio 2013 RTM or Update 1 does not overwrite the latest packages in your projects. If you use ASP.NET scaffolding after updating the packages of your projects to Web API 2.1 or ASP.NET MVC 5.1, make sure the versions of Web API and ASP.NET MVC are consistent.

Syntax Highlighting for Razor Views in Visual Studio 2013

If you update to ASP.NET MVC 5.1 RTM without updating Visual Studio 2013, you will not get Visual Studio editor support for syntax highlighting while editing the Razor views. You will need to update Visual Studio 2013 to get this support.

Type Renames

Some of the types used for attribute routing extensibility are renamed in 5.1 RTM.

OLD TYPE NAME (5.1 RC)	NEW TYPE NAME (5.1 RTM)
IDirectRouteProvider	IDirectRouteFactory
RouteProviderAttribute	RouteFactoryAttribute
DirectRouteProviderContext	DirectRouteFactoryContext

Bug Fixes

This release also includes several bug fixes. You can find the complete list here:

- 5.1.0 package
- 5.1.1 package

The 5.1.2 package contains IntelliSense updates but no bug fixes.

How to Upgrade an ASP.NET MVC 4 and Web API Project to ASP.NET MVC 5 and Web API 2

2/20/2020 • 5 minutes to read • Edit Online

by Rick Anderson

ASP.NET MVC 5 and Web API 2 bring a host of new features, including attribute routing, authentication filters, and much more. See https://www.asp.net/vnext for more details.

This walkthrough will guide you with the steps required to upgrade your application to the latest version.

> **NOTE**
>
> Please see ASP.NET and Web Tools for Visual Studio 2013 Release Notes for information on breaking changes from MVC 4 and Web API to the next version.

This article was written by Youngjune Hong and Rick Anderson (@RickAndMSFT)

Upgrade Steps

1. Backup your project. This walkthrough will require you to make changes to your project file, package configuration, and web.config files.

2. For upgrading from Web API to Web API 2, in global.asax, change:

   ```
   WebApiConfig.Register(GlobalConfiguration.Configuration);
   ```

   to

   ```
   GlobalConfiguration.Configure(WebApiConfig.Register);
   ```

3. Make sure all the packages that your projects use are compatible with MVC 5 and Web API 2. The following table shows the MVC 4 and Web API related packages than need to be changed. If you have a package that is dependent on one of the packages listed below, please contact the publishers to get the newer versions that are compatible with MVC 5 and Web API 2. If you have the source code for those packages, you should recompile them with the new assemblies of MVC 5 and Web API 2.

PACKAGE ID	OLD VERSION	NEW VERSION
Microsoft.AspNet.Razor	2.0.x.x	3.0.0
Microsoft.AspNet.WebPages	2.0.x.x	3.0.0
Microsoft.AspNet.WebPages.WebData	2.0.x.x	3.0.0
Microsoft.AspNet.WebPages.OAuth	2.0.x.x	3.0.0

PACKAGE ID	OLD VERSION	NEW VERSION
Microsoft.AspNet.Mvc	4.0.x.x	5.0.0
Microsoft.AspNet.Mvc.Facebook	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.Core	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.SelfHost	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.Client	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.OData	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.WebHost	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.Tracing	4.0.x.x	5.0.0
Microsoft.AspNet.WebApi.HelpPage	4.0.x.x	5.0.0
Microsoft.Net.Http	2.0.x.	2.2.x.
Microsoft.Data.OData	5.2.x	5.6.x
System.Spatial	5.2.x	5.6.x
Microsoft.Data.Edm	5.2.x	5.6.x
Microsoft.AspNet.Mvc.FixedDisplayModes	<o:p> </o:p>	Removed
Microsoft.AspNet.WebPages.Administration	<o:p> </o:p>	Removed
Microsoft-Web-Helpers	<o:p> </o:p>	Microsoft.AspNet.WebHelpers

> **NOTE**
>
> Microsoft-Web-Helpers has been replaced with Microsoft.AspNet.WebHelpers. You should remove the old package first, and then install the newer package.
>
> There is no cross version compatibility among major ASP.NET packages. For example, MVC 5 is compatible with only Razor 3, and not Razor 2.

4. Open your project in Visual Studio.

5. Remove any of the following ASP.NET NuGet packages that are installed. You will remove these using the Package Manager Console (PMC). To open the PMC, select the **Tools** menu and then select **NuGet Package Manager,** then select **Package Manager Console**. Your project might not include all of these.

   a. `Microsoft.AspNet.WebPages.Administration`
   This package is typically added when upgrading from MVC 3 to MVC 4. To remove it, run the following

command in the PMC:
`Uninstall-Package -Id Microsoft.AspNet.WebPages.Administration`

b. `Microsoft-Web-Helpers`
This package has been rebranded as `Microsoft.AspNet.WebHelpers`. To remove it, run the following command in the PMC:
`Uninstall-Package -Id Microsoft-Web-Helpers`

c. `Microsoft.AspNet.Mvc.FixedDisplayMode`
This package contains a work around for a bug in MVC 4 that has been fixed in MVC 5. To remove it, run the following command in the PMC:
`Uninstall-Package -Id Microsoft.AspNet.Mvc.FixedDisplayModes`

6. Upgrade all the ASP.NET NuGet packages using the PMC. In the PMC, run the following command:
`Update-Package`
The `Update-Package` command without any parameters will update every package. You can update packages individually by using the ID argument. For more information about the update command, run `get-help update-package`.

Update the Application *web.config* File

Be sure to make these changes in the app *web.config* file, not the *web.config* file in the *Views* folder.

Locate the `<runtime>/<assemblyBinding>` section, and make the following changes:

1. In the elements with the name attribute "System.Web.Mvc", change the version number from "4.0.0.0" to "5.0.0.0". (Two changes in that element.)

2. In elements with the name attribute "System.Web.Helpers" and "System.Web.WebPages" change the version number from "2.0.0.0" to "3.0.0.0". Four changes will occur, two in each of the elements.

```
<runtime>
  <assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">
    <!--Two elements removed for Clarity -->
    <dependentAssembly>
      <assemblyIdentity name="System.Web.Helpers" publicKeyToken="31bf3856ad364e35" />
      <bindingRedirect oldVersion="1.0.0.0-3.0.0.0" newVersion="3.0.0.0" />
    </dependentAssembly>
    <dependentAssembly>
      <assemblyIdentity name="System.Web.Mvc" publicKeyToken="31bf3856ad364e35" />
      <bindingRedirect oldVersion="1.0.0.0-5.0.0.0" newVersion="5.0.0.0" />
    </dependentAssembly>
    <dependentAssembly>
      <assemblyIdentity name="System.Web.WebPages" publicKeyToken="31bf3856ad364e35" />
      <bindingRedirect oldVersion="1.0.0.0-3.0.0.0" newVersion="3.0.0.0" />
    </dependentAssembly>
    <!--WebGrease element removed for Clarity -->
  </assemblyBinding
```

3. Locate the `<appSettings>` section and update the webpages:version from 2.0.0.0 to 3.0.0.0 as shown below:

```
<appSettings>
    <add key="webpages:Version" value="3.0.0.0" />
    <add key="webpages:Enabled" value="false" />
    <add key="PreserveLoginUrl" value="true" />
    <add key="ClientValidationEnabled" value="true" />
    <add key="UnobtrusiveJavaScriptEnabled" value="true" />
  </appSettings>
```

4. Remove any trust levels other than Full. For example:

```
<securityPolicy>
   <!--<trustLevel name="Medium"  policyFile="web_mediumtrust.config"/>-->
</securityPolicy>
```

Update the *web.config* files under the Views folder

If your application is using areas, you will also need to update each *web.config* file in the *Views* sub-folder of each Area folder.

1. Update all elements that contain "System.Web.Mvc" from version "4.0.0.0" to version "5.0.0.0".

```
<system.web.webPages.razor>
  <host factoryType="System.Web.Mvc.MvcWebRazorHostFactory, System.Web.Mvc, Version=5.0.0.0,
Culture=neutral, PublicKeyToken=31BF3856AD364E35" />
  <pages pageBaseType="System.Web.Mvc.WebViewPage">
    <namespaces>
      <add namespace="System.Web.Mvc" />
      <!--Elements removed for Clarity.-->
    </namespaces>
  </pages>
</system.web.webPages.razor>
```

```
-->
  <pages
      validateRequest="false"
      pageParserFilterType="System.Web.Mvc.ViewTypeParserFilter, System.Web.Mvc, Version=5.0.0.0,
Culture=neutral, PublicKeyToken=31BF3856AD364E35"
      pageBaseType="System.Web.Mvc.ViewPage, System.Web.Mvc, Version=5.0.0.0, Culture=neutral,
PublicKeyToken=31BF3856AD364E35"
      userControlBaseType="System.Web.Mvc.ViewUserControl, System.Web.Mvc, Version=5.0.0.0,
Culture=neutral, PublicKeyToken=31BF3856AD364E35">
    <controls>
      <add assembly="System.Web.Mvc, Version=5.0.0.0, Culture=neutral, PublicKeyToken=31BF3856AD364E35"
namespace="System.Web.Mvc" tagPrefix="mvc" />
    </controls>
  </pages>
</system.web>
```

2. Update all elements that contain "System.Web.WebPages.Razor" from version "2.0.0.0" to version"3.0.0.0". If this section contains "System.Web.WebPages", update those elements from version "2.0.0.0" to version"3.0.0.0"

```
<configuration>
  <configSections>
    <sectionGroup name="system.web.webPages.razor"
type="System.Web.WebPages.Razor.Configuration.RazorWebSectionGroup, System.Web.WebPages.Razor,
Version=3.0.0.0, Culture=neutral, PublicKeyToken=31BF3856AD364E35">
      <section name="host" type="System.Web.WebPages.Razor.Configuration.HostSection,
System.Web.WebPages.Razor, Version=3.0.0.0, Culture=neutral, PublicKeyToken=31BF3856AD364E35"
requirePermission="false" />
      <section name="pages" type="System.Web.WebPages.Razor.Configuration.RazorPagesSection,
System.Web.WebPages.Razor, Version=3.0.0.0, Culture=neutral, PublicKeyToken=31BF3856AD364E35"
requirePermission="false" />
    </sectionGroup>
  </configSections>
```

3. If you removed the `Microsoft-Web-Helpers` NuGet package in a previous step, install `Microsoft.AspNet.WebHelpers` with the following command in the PMC:

```
Install-Package -Id Microsoft.AspNet.WebHelpers
```

4. If your app uses the User.IsInRole() method, add the following to the *Web.config* file.

```
<system.webServer>
    <modules>
      <remove name="RoleManager" />
    </modules>
  </system.webServer>
```

Final Steps

Build and test the application.

Remove the MVC 4 project type GUID from the project files.

1. In Solution Explorer, right-click the project name and then select **Unload Project**.
2. Right-click the project and select Edit ProjectName.csproj.
3. Locate the `ProjectTypeGuids` element and then remove the MVC 4 project GUID, `{E3E379DF-F4C6-4180-9B81-6769533ABE47}`.
4. Save and close the open project file.
5. Right-click the project and select **Reload Project**.

Getting Started with ASP.NET MVC 4

2/20/2020 • 2 minutes to read • Edit Online

This tutorial series will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio.

- Intro to ASP.NET MVC 4
- Adding a Controller
- Adding a View
- Adding a Model
- Accessing Your Model's Data from a Controller
- Examining the Edit Methods and Edit View
- Adding a New Field to the Movie Model and Table
- Adding Validation to the Model
- Examining the Details and Delete Methods

Intro to ASP.NET MVC 4

2/20/2020 • 3 minutes to read • Edit Online

by Rick Anderson

An updated version if this tutorial is available here using Visual Studio 2013. The new tutorial uses ASP.NET MVC 5, which provides many improvements over this tutorial.

This tutorial will teach you the basics of building an ASP.NET MVC 4 Web application using Microsoft Visual Studio Express 2012 or Visual Web Developer 2010 Express Service Pack 1. Visual Studio 2012 is recommended, you won't need to install anything to complete the tutorial. If you are using Visual Studio 2010 you must install the components below. You can install all of them by clicking the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- WPI installer for ASP.NET MVC 4
- LocalDB
- SSDT

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the WPI installer for ASP.NET MVC 4 and the: Visual Studio 2010 prerequisites

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version.

In the tutorial you run the application in Visual Studio. You can also make the application available over the Internet by deploying it to a hosting provider. Microsoft offers free web hosting for up to 10 web sites in a free Windows Azure trial account. For information about how to deploy a Visual Studio web project to a Windows Azure Web Site, see Create and deploy an ASP.NET web site and SQL Database with Visual Studio. That tutorial also shows how to use Entity Framework Code First Migrations to deploy your SQL Server database to Windows Azure SQL Database (formerly SQL Azure).

This tutorial was written by Rick Anderson (@RickAndMSFT).

What You'll Build

NOTE

An updated version if this tutorial is available here using Visual Studio 2013. The new tutorial uses ASP.NET MVC 5, which provides many improvements over this tutorial.

You'll implement a simple movie-listing application that supports creating, editing, searching and listing movies from a database. Below are two screenshots of the application you'll build. It includes a page that displays a list of movies from a database:

The application also lets you add, edit, and delete movies, as well as see details about individual ones. All data-entry scenarios include validation to ensure that the data stored in the database is correct.

Getting Started

Start by running Visual Studio Express 2012 or Visual Web Developer 2010 Express. Most of the screen shots in this series use Visual Studio Express 2012, but you can complete this tutorial with Visual Studio 2010/SP1, Visual Studio 2012, Visual Studio Express 2012 or Visual Web Developer 2010 Express. Select **New Project** from the **Start** page.

Visual Studio is an IDE, or integrated development environment. Just like you use Microsoft Word to write documents, you'll use an IDE to create applications. In Visual Studio there's a toolbar along the top showing various options available to you. There's also a menu that provides another way to perform tasks in the IDE. (For example, instead of selecting **New Project** from the **Start** page, you can use the menu and select **File** > **New Project**.)

Creating Your First Application

You can create applications using either Visual Basic or Visual C# as the programming language. Select Visual C# on the left and then select **ASP.NET MVC 4 Web Application**. Name your project "MvcMovie" and then click **OK**.

In the **New ASP.NET MVC 4 Project** dialog box, select **Internet Application**. Leave **Razor** as the default view engine.

Click **OK**. Visual Studio used a default template for the ASP.NET MVC project you just created, so you have a working application right now without doing anything! This is a simple "Hello World!" project, and it's a good place to start your application.

From the **Debug** menu, select **Start Debugging**.

Notice that the keyboard shortcut to start debugging is F5.

F5 causes Visual Studio to start IIS Express and run your web application. Visual Studio then launches a browser and opens the application's home page. Notice that the address bar of the browser says `localhost` and not something like `example.com`. That's because `localhost` always points to your own local computer, which in this case is running the application you just built. When Visual Studio runs a web project, a random port is used for the web server. In the image below, the port number is 41788. When you run the application, you'll probably see a different port number.

Right out of the box this default template gives you Home, Contact and About pages. It also provides support to register and log in, and links to Facebook and Twitter. The next step is to change how this application works and learn a little bit about ASP.NET MVC. Close your browser and let's change some code.

NEXT

Adding a Controller

2/20/2020 • 3 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

MVC stands for *model-view-controller*. MVC is a pattern for developing applications that are well architected, testable and easy to maintain. MVC-based applications contain:

- **M** odels: Classes that represent the data of the application and that use validation logic to enforce business rules for that data.
- **V** iews: Template files that your application uses to dynamically generate HTML responses.
- **C** ontrollers: Classes that handle incoming browser requests, retrieve model data, and then specify view templates that return a response to the browser.

We'll be covering all these concepts in this tutorial series and show you how to use them to build an application.

Let's begin by creating a controller class. In **Solution Explorer**, right-click the *Controllers* folder and then select **Add Controller**.

Name your new controller "HelloWorldController". Leave the default template as **Empty MVC controller** and click **Add**.

Notice in **Solution Explorer** that a new file has been created named *HelloWorldController.cs*. The file is open in the IDE.

Replace the contents of the file with the following code.

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my <b>default</b> action...";
        }

        //
        // GET: /HelloWorld/Welcome/

        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

The controller methods will return a string of HTML as an example. The controller is named `HelloWorldController` and the first method above is named `Index`. Let's invoke it from a browser. Run the application (press F5 or Ctrl+F5). In the browser, append "HelloWorld" to the path in the address bar. (For example, in the illustration below, it's `http://localhost:1234/HelloWorld.`) The page in the browser will look like the following screenshot. In the method above, the code returned a string directly. You told the system to just return some HTML, and it did!

ASP.NET MVC invokes different controller classes (and different action methods within them) depending on the incoming URL. The default URL routing logic used by ASP.NET MVC uses a format like this to determine what code to invoke:

`/[Controller]/[ActionName]/[Parameters]`

The first part of the URL determines the controller class to execute. So */HelloWorld* maps to the `HelloWorldController` class. The second part of the URL determines the action method on the class to execute. So */HelloWorld/Index* would cause the `Index` method of the `HelloWorldController` class to execute. Notice that we only had to browse to */HelloWorld* and the `Index` method was used by default. This is because a method named `Index` is the default method that will be called on a controller if one is not explicitly specified.

Browse to `http://localhost:xxxx/HelloWorld/Welcome`. The `Welcome` method runs and returns the string "This is the Welcome action method...". The default MVC mapping is `/[Controller]/[ActionName]/[Parameters]`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.

Let's modify the example slightly so that you can pass some parameter information from the URL to the controller (for example, */HelloWorld/Welcome?name=Scott&numtimes=4*). Change your `Welcome` method to include two parameters as shown below. Note that the code uses the C# optional-parameter feature to indicate that the `numTimes` parameter should default to 1 if no value is passed for that parameter.

```
public string Welcome(string name, int numTimes = 1) {
     return HttpUtility.HtmlEncode("Hello " + name + ", NumTimes is: " + numTimes);
}
```

Run your application and browse to the example URL (`http://localhost:xxxx/HelloWorld/Welcome?name=Scott&numtimes=4)` . You can try different values for `name` and `numtimes` in the URL. The ASP.NET MVC model binding system automatically maps the named parameters from the query string in the address bar to parameters in your method.

In both these examples the controller has been doing the "VC" portion of MVC — that is, the view and controller work. The controller is returning HTML directly. Ordinarily you don't want controllers returning HTML directly, since that becomes very cumbersome to code. Instead we'll typically use a separate view template file to help generate the HTML response. Let's look next at how we can do this.

Adding a View

2/20/2020 • 8 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section you're going to modify the `HelloWorldController` class to use view template files to cleanly encapsulate the process of generating HTML responses to a client.

You'll create a view template file using the Razor view engine introduced with ASP.NET MVC 3. Razor-based view templates have a *.cshtml* file extension, and provide an elegant way to create HTML output using C#. Razor minimizes the number of characters and keystrokes required when writing a view template, and enables a fast, fluid coding workflow.

Currently the `Index` method returns a string with a message that is hard-coded in the controller class. Change the `Index` method to return a `View` object, as shown in the following code:

```
public ActionResult Index()
{
    return View();
}
```

The `Index` method above uses a view template to generate an HTML response to the browser. Controller methods (also known as action methods), such as the `Index` method above, generally return an ActionResult (or a class derived from ActionResult), not primitive types like string.

In the project, add a view template that you can use with the `Index` method. To do this, right-click inside the `Index` method and click **Add View**.

The **Add View** dialog box appears. Leave the defaults the way they are and click the **Add** button:

The *MvcMovie\Views\HelloWorld* folder and the *MvcMovie\Views\HelloWorld\Index.cshtml* file are created. You can see them in **Solution Explorer**:

The following shows the *Index.cshtml* file that was created:

Add the following HTML under the `<h2>` tag.

```
<p>Hello from our View Template!</p>
```

The complete *MvcMovie\Views\HelloWorld\Index.cshtml* file is shown below.

```
@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

If you are using Visual Studio 2012, in solution explorer, right click the *Index.cshtml* file and select **View in Page Inspector**.

The Page Inspector tutorial has more information about this new tool.

Alternatively, run the application and browse to the `HelloWorld` controller (`http://localhost:xxxx/HelloWorld`). The `Index` method in your controller didn't do much work; it simply ran the statement `return View()`, which specified that the method should use a view template file to render a response to the browser. Because you didn't explicitly specify the name of the view template file to use, ASP.NET MVC defaulted to using the *Index.cshtml* view file in the *\Views\HelloWorld* folder. The image below shows the string "Hello from our View Template!" hard-coded in the view.

Looks pretty good. However, notice that the browser's title bar shows "Index My ASP.NET A" and the big link on the top of the page says "your logo here." Below the "your logo here." link are registration and log in links, and below that links to Home, About and Contact pages. Let's change some of these.

Changing Views and Layout Pages

First, you want to change the "your logo here." title at the top of the page. That text is common to every page. It's actually implemented in only one place in the project, even though it appears on every page in the application. Go to the */Views/Shared* folder in **Solution Explorer** and open the *_Layout.cshtml* file. This file is called a *layout page* and it's the shared "shell" that all other pages use.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Find the `@RenderBody()` line. `RenderBody` is a placeholder where all the view-specific pages you create show up, "wrapped" in the layout page. For example, if you select the About link, the *Views\Home\About.cshtml* view is rendered inside the `RenderBody` method.

Change the site-title heading in the layout template from "your logo here" to "MVC Movie".

```
<div class="float-left">
    <p class="site-title">@Html.ActionLink("MVC Movie", "Index", "Home")</p>
</div>
```

Replace the contents of the title element with the following markup:

```
<title>@ViewBag.Title - Movie App</title>
```

Run the application and notice that it now says "MVC Movie ". Click the **About** link, and you see how that page shows "MVC Movie", too. We were able to make the change once in the layout template and have all pages on the site reflect the new title.

Now, let's change the title of the Index view.

Open *MvcMovie\Views\HelloWorld\Index.cshtml*. There are two places to make a change: first, the text that appears in the title of the browser, and then in the secondary header (the `<h2>` element). You'll make them slightly different so you can see which bit of code changes which part of the app.

```
@{
    ViewBag.Title = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

To indicate the HTML title to display, the code above sets a `Title` property of the `ViewBag` object (which is in the *Index.cshtml* view template). If you look back at the source code of the layout template, you'll notice that the template uses this value in the `<title>` element as part of the `<head>` section of the HTML that we modified previously. Using this `ViewBag` approach, you can easily pass other parameters between your view template and your layout file.

Run the application and browse to `http://localhost:xx/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.) The browser title is created with the `ViewBag.Title` we set in the *Index.cshtml* view template and the additional "-Movie App" added in the layout file.

Also notice how the content in the *Index.cshtml* view template was merged with the *_Layout.cshtml* view template and a single HTML response was sent to the browser. Layout templates make it really easy to make changes that apply across all of the pages in your application.

Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet. Shortly, we'll walk through how create a database and retrieve model data from it.

Passing Data from the Controller to the View

Before we go to a database and talk about models, though, let's first talk about passing information from the controller to a view. Controller classes are invoked in response to an incoming URL request. A controller class is where you write the code that handles the incoming browser requests, retrieves data from a database, and ultimately decides what type of response to send back to the browser. View templates can then be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing whatever data or objects are required in order for a view template to render a response to the browser. A best practice: **A view template should never perform business logic or interact with a database directly**. Instead, a view template should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep your code clean, testable and more maintainable.

Currently, the `Welcome` action method in the `HelloWorldController` class takes a `name` and a `numTimes` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, let's change the controller to use a view template instead. The view template will generate a dynamic response, which means that you need to pass appropriate bits of data from the controller to the view in order to generate the response. You can do this by having the controller put the dynamic data (parameters) that the view template needs in a `ViewBag` object that the view template can then access.

Return to the *HelloWorldController.cs* file and change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewBag` object. `ViewBag` is a dynamic object, which means you can put whatever you want in to it; the `ViewBag` object has no defined properties until you put something inside it. The ASP.NET MVC model binding system automatically maps the named parameters (`name` and `numTimes`) from the query string in the address bar to parameters in your method. The complete *HelloWorldController.cs* file looks like this:

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult Welcome(string name, int numTimes = 1)
        {
            ViewBag.Message = "Hello " + name;
            ViewBag.NumTimes = numTimes;

            return View();
        }
    }
}
```

Now the `ViewBag` object contains data that will be passed to the view automatically.

Next, you need a Welcome view template! In the **Build** menu, select **Build MvcMovie** to make sure the project is compiled.

Then right-click inside the `Welcome` method and click **Add View**.

Here's what the **Add View** dialog box looks like:

Click **Add**, and then add the following code under the `<h2>` element in the new *Welcome.cshtml* file. You'll create a loop that says "Hello" as many times as the user says it should. The complete *Welcome.cshtml* file is shown below.

```
@{
    ViewBag.Title = "Welcome";
}

<h2>Welcome</h2>

<ul>
   @for (int i=0; i < ViewBag.NumTimes; i++) {
      <li>@ViewBag.Message</li>
   }
</ul>
```

Run the application and browse to the following URL:

`http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4`

Now data is taken from the URL and passed to the controller using the model binder. The controller packages the data into a `ViewBag` object and passes that object to the view. The view then displays the data as HTML to the user.

In the sample above, we used a `ViewBag` object to pass data from the controller to a view. Latter in the tutorial, we will use a view model to pass data from a controller to a view. The view model approach to passing data is generally much preferred over the view bag approach. See the blog entry Dynamic V Strongly Typed Views for more information.

Well, that was a kind of an "M" for model, but not the database kind. Let's take what we've learned and create a database of movies.

PREVIOUS NEXT

Adding a Model

2/20/2020 • 2 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section you'll add some classes for managing movies in a database. These classes will be the "model" part of the ASP.NET MVC application.

You'll use a .NET Framework data-access technology known as the Entity Framework to define and work with these model classes. The Entity Framework (often referred to as EF) supports a development paradigm called *Code First*. Code First allows you to create model objects by writing simple classes. (These are also known as POCO classes, from "plain-old CLR objects.") You can then have the database created on the fly from your classes, which enables a very clean and rapid development workflow.

Adding Model Classes

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Enter the *class* name "Movie".

Add the following five properties to the `Movie` class:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
}
```

We'll use the `Movie` class to represent movies in a database. Each instance of a `Movie` object will correspond to a row within a database table, and each property of the `Movie` class will map to a column in the table.

In the same file, add the following `MovieDBContext` class:

```
public class MovieDBContext : DbContext
{
    public DbSet<Movie> Movies { get; set; }
}
```

The `MovieDBContext` class represents the Entity Framework movie database context, which handles fetching, storing, and updating `Movie` class instances in a database. The `MovieDBContext` derives from the `DbContext` base class provided by the Entity Framework.

In order to be able to reference `DbContext` and `DbSet`, you need to add the following `using` statement at the top of the file:

```
using System.Data.Entity;
```

The complete *Movie.cs* file is shown below. (Several using statements that are not needed have been removed.)

```
using System;
using System.Data.Entity;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

Creating a Connection String and Working with SQL Server LocalDB

The `MovieDBContext` class you created handles the task of connecting to the database and mapping `Movie` objects to database records. One question you might ask, though, is how to specify which database it will connect to. You'll do that by adding connection information in the *Web.config* file of the application.

Open the application root *Web.config* file. (Not the *Web.config* file in the *Views* folder.) Open the *Web.config* file outlined in red.

Add the following connection string to the `<connectionStrings>` element in the *Web.config* file.

```
<add name="MovieDBContext"
   connectionString="Data Source=(LocalDB)\v11.0;AttachDbFilename=|DataDirectory|\Movies.mdf;Integrated
Security=True"
   providerName="System.Data.SqlClient"
/>
```

The following example shows a portion of the *Web.config* file with the new connection string added:

```
<connectionStrings>
  <add name="DefaultConnection"
       connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=aspnet-MvcMovie-2012213181139;Integrated
Security=true"
       providerName="System.Data.SqlClient"
  />
  <add name="MovieDBContext"
       connectionString="Data Source=(LocalDB)\v11.0;AttachDbFilename=|DataDirectory|\Movies.mdf;Integrated
Security=True"
       providerName="System.Data.SqlClient"
  />
</connectionStrings>
```

This small amount of code and XML is everything you need to write in order to represent and store the movie data in a database.

Next, you'll build a new `MoviesController` class that you can use to display the movie data and allow users to create new movie listings.

PREVIOUS NEXT

Accessing Your Model's Data from a Controller

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section, you'll create a new `MoviesController` class and write code that retrieves the movie data and displays it in the browser using a view template.

Build the application before going on to the next step.

Right-click the *Controllers* folder and create a new `MoviesController` controller. The options below will not appear until you build your application. Select the following options:

- Controller name: **MoviesController**. (This is the default.)
- Template: **MVC Controller with read/write actions and views, using Entity Framework**.
- Model class: **Movie (MvcMovie.Models)**.
- Data context class: **MovieDBContext (MvcMovie.Models)**.
- Views: **Razor (CSHTML)**. (The default.)

Click **Add**. Visual Studio Express creates the following files and folders:

- *A MoviesController.cs* file in the project's *Controllers* folder.
- A *Movies* folder in the project's *Views* folder.
- *Create.cshtml, Delete.cshtml, Details.cshtml, Edit.cshtml*, and *Index.cshtml* in the new *Views\Movies* folder.

ASP.NET MVC 4 automatically created the CRUD (create, read, update, and delete) action methods and views for you (the automatic creation of CRUD action methods and views is known as scaffolding). You now have a fully

functional web application that lets you create, list, edit, and delete movie entries.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Because the application is relying on the default routing (defined in the *Global.asax* file), the browser request `http://localhost:xxxxx/Movies` is routed to the default `Index` action method of the `Movies` controller. In other words, the browser request `http://localhost:xxxxx/Movies` is effectively the same as the browser request `http://localhost:xxxxx/Movies/Index`. The result is an empty list of movies, because you haven't added any yet.

Creating a Movie

Select the **Create New** link. Enter some details about a movie and then click the **Create** button.

Clicking the **Create** button causes the form to be posted to the server, where the movie information is saved in the database. You're then redirected to the */Movies* URL, where you can see the newly created movie in the listing.

Create a couple more movie entries. Try the **Edit**, **Details**, and **Delete** links, which are all functional.

Examining the Generated Code

Open the *Controllers\MoviesController.cs* file and examine the generated `Index` method. A portion of the movie controller with the `Index` method is shown below.

```
public class MoviesController : Controller
{
    private MovieDBContext db = new MovieDBContext();

    //
    // GET: /Movies/

    public ActionResult Index()
    {
        return View(db.Movies.ToList());
    }
```

The following line from the `MoviesController` class instantiates a movie database context, as described previously. You can use the movie database context to query, edit, and delete movies.

```
private MovieDBContext db = new MovieDBContext();
```

A request to the `Movies` controller returns all the entries in the `Movies` table of the movie database and then passes the results to the `Index` view.

Strongly Typed Models and the @model Keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view template using the `ViewBag` object. The `ViewBag` is a dynamic object that provides a convenient late-bound way to pass information to a view.

ASP.NET MVC also provides the ability to pass strongly typed data or objects to a view template. This strongly typed approach enables better compile-time checking of your code and richer IntelliSense in the Visual Studio editor. The scaffolding mechanism in Visual Studio used this approach with the `MoviesController` class and view templates when it created the methods and views.

In the *Controllers\MoviesController.cs* file examine the generated `Details` method. A portion of the movie controller with the `Details` method is shown below.

```
public ActionResult Details(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

If a `Movie` is found, an instance of the `Movie` model is passed to the Details view. Examine the contents of the *Views\Movies\Details.cshtml* file.

By including a `@model` statement at the top of the view template file, you can specify the type of object that the view expects. When you created the movie controller, Visual Studio automatically included the following `@model` statement at the top of the *Details.cshtml* file:

```
@model MvcMovie.Models.Movie
```

This `@model` directive allows you to access the movie that the controller passed to the view by using a `Model`

object that's strongly typed. For example, in the *Details.cshtml* template, the code passes each movie field to the `DisplayNameFor` and DisplayFor HTML Helpers with the strongly typed `Model` object. The Create and Edit methods and view templates also pass a movie model object.

Examine the *Index.cshtml* view template and the `Index` method in the *MoviesController.cs* file. Notice how the code creates a `List` object when it calls the `View` helper method in the `Index` action method. The code then passes this `Movies` list from the controller to the view:

```
public ActionResult Index()
{
    return View(db.Movies.ToList());
}
```

When you created the movie controller, Visual Studio Express automatically included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

This `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* template, the code loops through the movies by doing a `foreach` statement over the strongly typed `Model` object:

```
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
         <th>
            @Html.DisplayFor(modelItem => item.Rating)
        </th>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", { id=item.ID })  |
            @Html.ActionLink("Delete", "Delete", { id=item.ID })
        </td>
    </tr>
}
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each `item` object in the loop is typed as `Movie`. Among other benefits, this means that you get compile-time checking of the code and full IntelliSense support in the code editor:

Working with SQL Server LocalDB

Entity Framework Code First detected that the database connection string that was provided pointed to a `Movies` database that didn't exist yet, so Code First created the database automatically. You can verify that it's been created by looking in the *App_Data* folder. If you don't see the *Movies.mdf* file, click the **Show All Files** button in the **Solution Explorer** toolbar, click the **Refresh** button, and then expand the *App_Data* folder.

Double-click *Movies.mdf* to open **DATABASE EXPLORER**, then expand the **Tables** folder to see the Movies table.

> **NOTE**
>
> If the database explorer doesn't appear, from the **TOOLS** menu, select **Connect to Database**, then cancel the **Choose Data Source** dialog. This will force open the database explorer.

> **NOTE**
>
> If you are using VWD or Visual Studio 2010 and get an error similar to any of the following following:
>
> - The database 'C:\Webs\MVC4\MVCMOVIE\MVCMOVIE\APP_DATA\MOVIES.MDF' cannot be opened because it is version 706. This server supports version 655 and earlier. A downgrade path is not supported.
> - "InvalidOperation Exception was unhandled by user code" The supplied SqlConnection does not specify an initial catalog.
>
> You need to install the SQL Server Data Tools and LocalDB. Verify the `MovieDBContext` connection string specified on the previous page.

Right-click the `Movies` table and select **Show Table Data** to see the data you created.

Right-click the `Movies` table and select **Open Table Definition** to see the table structure that Entity Framework Code First created for you.

Notice how the schema of the `Movies` table maps to the `Movie` class you created earlier. Entity Framework Code First automatically created this schema for you based on your `Movie` class.

When you're finished, close the connection by right clicking *MovieDBContext* and selecting **Close Connection**. (If you don't close the connection, you might get an error the next time you run the project).

You now have the database and a simple listing page to display content from it. In the next tutorial, we'll examine the rest of the scaffolded code and add a `SearchIndex` method and a `SearchIndex` view that lets you search for movies in this database.

PREVIOUS NEXT

Examining the Edit Methods and Edit View

9/16/2020 • 14 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section, you'll examine the generated action methods and views for the movie controller. Then you'll add a custom search page.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Hold the mouse pointer over an **Edit** link to see the URL that it links to.

The **Edit** link was generated by the `Html.ActionLink` method in the *Views\Movies\Index.cshtml* view:

```
@Html.ActionLink("Edit", "Edit", new { id=item.ID })
```

```
<td>
    @Html.ActionLink("Edit Me", "Edit", new { id=item.ID }) |
    @Html.
    @Html.
```

(extension) MvcHtmlString HtmlHelper.ActionLink(string linkText, string actionName, object routeValues)
Returns an anchor element (a element) that contains the virtual path of the specified action.

Exceptions:
System.ArgumentException

The `Html` object is a helper that's exposed using a property on the System.Web.Mvc.WebViewPage base class. The `ActionLink` method of the helper makes it easy to dynamically generate HTML hyperlinks that link to action methods on controllers. The first argument to the `ActionLink` method is the link text to render (for example, `<a>Edit Me</a>`). The second argument is the name of the action method to invoke. The final argument is an anonymous object that generates the route data (in this case, the ID of 4).

The generated link shown in the previous image is `http://localhost:xxxxx/Movies/Edit/4`. The default route (established in *App_Start\RouteConfig.cs*) takes the URL pattern `{controller}/{action}/{id}`. Therefore, ASP.NET translates `http://localhost:xxxxx/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `ID` equal to 4. Examine the following code from the *App_Start\RouteConfig.cs* file.

```
public static void RegisterRoutes(RouteCollection routes)
{
    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        name: "Default",
        url: "{controller}/{action}/{id}",
        defaults: new { controller = "Home", action = "Index",
            id = UrlParameter.Optional }
    );
}
```

You can also pass action method parameters using a query string. For example, the URL `http://localhost:xxxxx/Movies/Edit?ID=4` also passes the parameter `ID` of 4 to the `Edit` action method of the `Movies` controller.

Open the `Movies` controller. The two `Edit` action methods are shown below.

```
//
// GET: /Movies/Edit/5

public ActionResult Edit(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}

//
// POST: /Movies/Edit/5

[HttpPost]
public ActionResult Edit(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

Notice the second `Edit` action method is preceded by the `HttpPost` attribute. This attribute specifies that overload of the `Edit` method can be invoked only for POST requests. You could apply the `HttpGet` attribute to the first edit method, but that's not necessary because it's the default. (We'll refer to action methods that are implicitly assigned the `HttpGet` attribute as `HttpGet` methods.)

The `HttpGet` `Edit` method takes the movie ID parameter, looks up the movie using the Entity Framework `Find` method, and returns the selected movie to the Edit view. The ID parameter specifies a default value of zero if the `Edit` method is called without a parameter. If a movie cannot be found, HttpNotFound is returned. When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated:

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Edit";
}

<h2>Edit</h2>

@using (Html.BeginForm()) {
    @Html.ValidationSummary(true)

    <fieldset>
        <legend>Movie</legend>

        @Html.HiddenFor(model => model.ID)

        <div class="editor-label">
            @Html.LabelFor(model => model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Title)
            @Html.ValidationMessageFor(model => model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.ReleaseDate)
            @Html.ValidationMessageFor(model => model.ReleaseDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Genre)
            @Html.ValidationMessageFor(model => model.Genre)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Price)
            @Html.ValidationMessageFor(model => model.Price)
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file — this specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several *helper methods* to streamline the HTML markup. The `Html.LabelFor` helper

displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The `Html.EditorFor` helper renders an HTML `<input>` element. The `Html.ValidationMessageFor` helper displays any validation messages associated with that property.

Run the application and navigate to the */Movies* URL. Click an **Edit** link. In the browser, view the source for the page. The HTML for the form element is shown below.

```
<form action="/Movies/Edit/4" method="post">    <fieldset>
        <legend>Movie</legend>

        <input data-val="true" data-val-number="The field ID must be a number." data-val-required="The ID
field is required." id="ID" name="ID" type="hidden" value="4" />

        <div class="editor-label">
            <label for="Title">Title</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Title" name="Title" type="text" value="Rio Bravo" />
            <span class="field-validation-valid" data-valmsg-for="Title" data-valmsg-replace="true"></span>
        </div>

        <div class="editor-label">
            <label for="ReleaseDate">ReleaseDate</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" data-val="true" data-val-date="The field ReleaseDate must be a
date." data-val-required="The ReleaseDate field is required." id="ReleaseDate" name="ReleaseDate" type="text"
value="4/15/1959 12:00:00 AM" />
            <span class="field-validation-valid" data-valmsg-for="ReleaseDate" data-valmsg-replace="true">
</span>
        </div>

        <div class="editor-label">
            <label for="Genre">Genre</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Genre" name="Genre" type="text" value="Western" />
            <span class="field-validation-valid" data-valmsg-for="Genre" data-valmsg-replace="true">></span>
        </div>

        <div class="editor-label">
            <label for="Price">Price</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" data-val="true" data-val-number="The field Price must be a
number." data-val-required="The Price field is required." id="Price" name="Price" type="text" value="2.99" />
            <span class="field-validation-valid" data-valmsg-for="Price" data-valmsg-replace="true"></span>
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
</form>
```

The `<input>` elements are in an HTML `<form>` element whose `action` attribute is set to post to the */Movies/Edit* URL. The form data will be posted to the server when the **Edit** button is clicked.

Processing the POST Request

The following listing shows the `HttpPost` version of the `Edit` action method.

```
[HttpPost]
public ActionResult Edit(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The ASP.NET MVC model binder takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` method verifies that the data submitted in the form can be used to modify (edit or update) a `Movie` object. If the data is valid, the movie data is saved to the `Movies` collection of the `db(MovieDBContext` instance). The new movie data is saved to the database by calling the `SaveChanges` method of `MovieDBContext`. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which displays the of movie collection, including the changes just made.

If the posted values aren't valid, they are redisplayed in the form. The `Html.ValidationMessageFor` helpers in the *Edit.cshtml* view template take care of displaying appropriate error messages.

NOTE

to support jQuery validation for non-English locales that use a comma (",") for a decimal point, you must include *globalize.js* and your specific *cultures/globalize.cultures.js* file(from https://github.com/jquery/globalize) and JavaScript to use `Globalize.parseFloat`. The following code shows the modifications to the Views\Movies\Edit.cshtml file to work with the "fr-FR" culture:

```
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
    <script src="~/Scripts/globalize.js"></script>
    <script src="~/Scripts/globalize.culture.fr-FR.js"></script>
    <script>
        $.validator.methods.number = function (value, element) {
            return this.optional(element) ||
                !isNaN(Globalize.parseFloat(value));
        }
        $(document).ready(function () {
            Globalize.culture('fr-FR');
        });
    </script>
    <script>
        jQuery.extend(jQuery.validator.methods, {
            range: function (value, element, param) {
                //Use the Globalization plugin to parse the value
                var val = $.global.parseFloat(value);
                return this.optional(element) || (
                    val >= param[0] && val <= param[1]);
            }
        });

    </script>
}
```

The decimal field may require a comma, not a decimal point. As a temporary fix, you can add the globalization element to the projects root web.config file. The following code shows the globalization element with the culture set to United States English.

```
<system.web>
    <globalization culture ="en-US" />
    <!--elements removed for clarity-->
  </system.web>
```

All the `HttpGet` methods follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the model to the view. The `Create` method passes an empty movie object to the Create view. All the methods that create, edit, delete, or otherwise modify data do so in the `HttpPost` overload of the method. Modifying data in an HTTP GET method is a security risk, as described in the blog post entry ASP.NET MVC Tip #46 – Don't use Delete Links because they create Security Holes. Modifying data in a GET method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests should not change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects and doesn't modify your persisted data.

Adding a Search Method and Search View

In this section you'll add a `SearchIndex` action method that lets you search movies by genre or name. This will be available using the */Movies/SearchIndex* URL. The request will display an HTML form that contains input elements that a user can enter in order to search for a movie. When a user submits the form, the action method will get the search values posted by the user and use the values to search the database.

Displaying the SearchIndex Form

Start by adding a `SearchIndex` action method to the existing `MoviesController` class. The method will return a view that contains an HTML form. Here's the code:

```
public ActionResult SearchIndex(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

The first line of the `SearchIndex` method creates the following LINQ query to select the movies:

```
var movies = from m in db.Movies
             select m;
```

The query is defined at this point, but hasn't yet been run against the data store.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string, using the following code:

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s => s.Title.Contains(searchString));
}
```

The `s => s.Title` code above is a Lambda Expression. Lambdas are used in method-based LINQ queries as arguments to standard query operator methods such as the Where method used in the above code. LINQ queries are not executed when they are defined or when they are modified by calling a method such as `Where` or `OrderBy` . Instead, query execution is deferred, which means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToList` method is called. In the `SearchIndex` sample, the query is executed in the SearchIndex view. For more information about deferred query execution, see Query Execution.

Now you can implement the `SearchIndex` view that will display the form to the user. Right-click inside the `SearchIndex` method and then click **Add View**. In the **Add View** dialog box, specify that you're going to pass a `Movie` object to the view template as its model class. In the **Scaffold template** list, choose **List**, then click **Add**.

When you click the **Add** button, the *Views\Movies\SearchIndex.cshtml* view template is created. Because you selected **List** in the **Scaffold template** list, Visual Studio automatically generated (scaffolded) some default markup in the view. The scaffolding created an HTML form. It examined the `Movie` class and created code to render `<label>` elements for each property of the class. The listing below shows the Create view that was generated:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "SearchIndex";
}

<h2>SearchIndex</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th>
            Title
        </th>
        <th>
            ReleaseDate
        </th>
        <th>
            Genre
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}

</table>
```

Run the application and navigate to */Movies/SearchIndex*. Append a query string such as `?searchString=ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `SearchIndex` method to have a parameter named `id`, the `id` parameter will match the `{id}` placeholder for the default routes set in the *Global.asax* file.

```
{controller}/{action}/{id}
```

The original `SearchIndex` method looks like this::

```
public ActionResult SearchIndex(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

The modified `SearchIndex` method would look as follows:

```
public ActionResult SearchIndex(string id)
{
    string searchString = id;
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you you'll add UI to help them filter movies. If you changed the signature of the `SearchIndex` method to test how to pass the route-bound ID parameter, change it back so that your `SearchIndex` method takes a string parameter named `searchString`:

```
public ActionResult SearchIndex(string searchString)
{
     var movies = from m in db.Movies
                  select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

Open the *Views\Movies\SearchIndex.cshtml* file, and just after `@Html.ActionLink("Create New", "Create")`, add the

following:

```
@using (Html.BeginForm()){
         <p> Title: @Html.TextBox("SearchString")<br />
         <input type="submit" value="Filter" /></p>
        }
```

The following example shows a portion of the *Views\Movies\SearchIndex.cshtml* file with the added filtering markup.

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "SearchIndex";
}

<h2>SearchIndex</h2>

<p>
    @Html.ActionLink("Create New", "Create")

     @using (Html.BeginForm()){
         <p> Title: @Html.TextBox("SearchString") <br />
         <input type="submit" value="Filter" /></p>
        }
</p>
```

The `Html.BeginForm` helper creates an opening `<form>` tag. The `Html.BeginForm` helper causes the form to post to itself when the user submits the form by clicking the **Filter** button.

Run the application and try searching for a movie.

There's no `HttpPost` overload of the `SearchIndex` method. You don't need it, because the method isn't changing the state of the application, just filtering data.

You could add the following `HttpPost SearchIndex` method. In that case, the action invoker would match the `HttpPost SearchIndex` method, and the `HttpPost SearchIndex` method would run as shown in the image below.

```
[HttpPost]
public string SearchIndex(FormCollection fc, string searchString)
{
    return "<h3> From [HttpPost]SearchIndex: " + searchString + "</h3>";
}
```

However, even if you add this `HttpPost` version of the `SearchIndex` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends

that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:xxxxx/Movies/SearchIndex) -- there's no search information in the URL itself. Right now, the search string information is sent to the server as a form field value. This means you can't capture that search information to bookmark or send to friends in a URL.

The solution is to use an overload of `BeginForm` that specifies that the POST request should add the search information to the URL and that it should be routed to the HttpGet version of the `SearchIndex` method. Replace the existing parameterless `BeginForm` method with the following:

```
@using (Html.BeginForm("SearchIndex","Movies",FormMethod.Get))
```

Now when you submit a search, the URL contains a search query string. Searching will also go to the `HttpGet SearchIndex` action method, even if you have a `HttpPost SearchIndex` method.

Adding Search by Genre

If you added the `HttpPost` version of the `SearchIndex` method, delete it now.

Next, you'll add a feature to let users search for movies by genre. Replace the `SearchIndex` method with the following code:

```
public ActionResult SearchIndex(string movieGenre, string searchString)
{
    var GenreLst = new List<string>();

    var GenreQry = from d in db.Movies
                   orderby d.Genre
                   select d.Genre;
    GenreLst.AddRange(GenreQry.Distinct());
    ViewBag.movieGenre = new SelectList(GenreLst);

    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (string.IsNullOrEmpty(movieGenre))
        return View(movies);
    else
    {
        return View(movies.Where(x => x.Genre == movieGenre));
    }

}
```

This version of the `SearchIndex` method takes an additional parameter, namely `movieGenre`. The first few lines of code create a `List` object to hold movie genres from the database.

The following code is a LINQ query that retrieves all the genres from the database.

```
var GenreQry = from d in db.Movies
                   orderby d.Genre
                   select d.Genre;
```

The code uses the `AddRange` method of the generic `List` collection to add all the distinct genres to the list. (Without the `Distinct` modifier, duplicate genres would be added — for example, comedy would be added twice in our sample). The code then stores the list of genres in the `ViewBag` object.

The following code shows how to check the `movieGenre` parameter. If it's not empty, the code further constrains the movies query to limit the selected movies to the specified genre.

```
if (string.IsNullOrEmpty(movieGenre))
        return View(movies);
else
{
    return View(movies.Where(x => x.Genre == movieGenre));
}
```

Adding Markup to the SearchIndex View to Support Search by Genre

Add an `Html.DropDownList` helper to the *Views\Movies\SearchIndex.cshtml* file, just before the `TextBox` helper. The completed markup is shown below:

```
<p>
    @Html.ActionLink("Create New", "Create")
    @using (Html.BeginForm("SearchIndex","Movies",FormMethod.Get)){
         <p>Genre: @Html.DropDownList("movieGenre", "All")
           Title: @Html.TextBox("SearchString")
         <input type="submit" value="Filter" /></p>
        }
</p>
```

Run the application and browse to */Movies/SearchIndex*. Try a search by genre, by movie name, and by both criteria.

In this section you examined the CRUD action methods and views generated by the framework. You created a search action method and view that let users search by movie title and genre. In the next section, you'll look at how to add a property to the `Movie` model and how to add an initializer that will automatically create a test database.

Adding a New Field to the Movie Model and Table

2/20/2020 • 8 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section you'll use Entity Framework Code First Migrations to migrate some changes to the model classes so the change is applied to the database.

By default, when you use Entity Framework Code First to automatically create a database, as you did earlier in this tutorial, Code First adds a table to the database to help track whether the schema of the database is in sync with the model classes it was generated from. If they aren't in sync, the Entity Framework throws an error. This makes it easier to track down issues at development time that you might otherwise only find (by obscure errors) at run time.

Setting up Code First Migrations for Model Changes

If you are using Visual Studio 2012, double click the *Movies.mdf* file from Solution Explorer to open the database tool. Visual Studio Express for Web will show Database Explorer, Visual Studio 2012 will show Server Explorer. If you are using Visual Studio 2010, use SQL Server Object Explorer.

In the database tool (Database Explorer, Server Explorer or SQL Server Object Explorer), right click on `MovieDBContext` and select **Delete** to drop the movies database.

Navigate back to Solution Explorer. Right click on the *Movies.mdf* file and select **Delete** to remove the movies database.

Build the application to make sure there are no errors.

From the **Tools** menu, click **NuGet Package Manager** and then **Package Manager Console**.

In the **Package Manager Console** window at the `PM>` prompt enter "Enable-Migrations -ContextTypeName MvcMovie.Models.MovieDBContext".

The **Enable-Migrations** command (shown above) creates a *Configuration.cs* file in a new *Migrations* folder.

Visual Studio opens the *Configuration.cs* file. Replace the `Seed` method in the *Configuration.cs* file with the following code:

```
protected override void Seed(MvcMovie.Models.MovieDBContext context)
{
    context.Movies.AddOrUpdate( i => i.Title,
        new Movie
        {
            Title = "When Harry Met Sally",
            ReleaseDate = DateTime.Parse("1989-1-11"),
            Genre = "Romantic Comedy",
            Price = 7.99M
        },

         new Movie
         {
             Title = "Ghostbusters ",
             ReleaseDate = DateTime.Parse("1984-3-13"),
             Genre = "Comedy",
             Price = 8.99M
         },

         new Movie
         {
             Title = "Ghostbusters 2",
             ReleaseDate = DateTime.Parse("1986-2-23"),
             Genre = "Comedy",
             Price = 9.99M
         },

        new Movie
        {
            Title = "Rio Bravo",
            ReleaseDate = DateTime.Parse("1959-4-15"),
            Genre = "Western",
            Price = 3.99M
        }
    );

}
```

Right click on the red squiggly line under `Movie` and select **Resolve** then **using MvcMovie.Models;**

Doing so adds the following using statement:

```
using MvcMovie.Models;
```

> **NOTE**
> Code First Migrations calls the `Seed` method after every migration (that is, calling **update-database** in the Package Manager Console), and this method updates rows that have already been inserted, or inserts them if they don't exist yet.

Press CTRL-SHIFT-B to build the project.(The following steps will fail if your don't build at this point.)

The next step is to create a `DbMigration` class for the initial migration. This migration to creates a new database, that's why you deleted the *movie.mdf* file in a previous step.

In the **Package Manager Console** window, enter the command "add-migration Initial" to create the initial migration. The name "Initial" is arbitrary and is used to name the migration file created.

Code First Migrations creates another class file in the *Migrations* folder (with the name *{DateStamp}_Initial.cs*), and this class contains code that creates the database schema. The migration filename is pre-fixed with a timestamp to help with ordering. Examine the *{DateStamp}_Initial.cs* file, it contains the instructions to create the Movies table for the Movie DB. When you update the database in the instructions below, this *{DateStamp}_Initial.cs* file will run and create the DB schema. Then the **Seed** method will run to populate the DB with test data.

In the **Package Manager Console**, enter the command "update-database" to create the database and run the **Seed** method.

If you get an error that indicates a table already exists and can't be created, it is probably because you ran the application after you deleted the database and before you executed `update-database`. In that case, delete the *Movies.mdf* file again and retry the `update-database` command. If you still get an error, delete the migrations folder and contents then start with the instructions at the top of this page (that is delete the *Movies.mdf* file then proceed to Enable-Migrations).

Run the application and navigate to the */Movies* URL. The seed data is displayed.

Adding a Rating Property to the Movie Model

Start by adding a new `Rating` property to the existing `Movie` class. Open the *Models\Movie.cs* file and add the `Rating` property like this one:

```
public string Rating { get; set; }
```

The complete `Movie` class now looks like the following code:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
    public string Rating { get; set; }
}
```

Build the application using the **Build** >**Build Movie** menu command or by pressing CTRL-SHIFT-B.

Now that you've updated the `Model` class, you also need to update the *\Views\Movies\Index.cshtml* and *\Views\Movies\Create.cshtml* view templates in order to display the new `Rating` property in the browser view.

Open the *\Views\Movies\Index.cshtml* file and add a `<th>Rating</th>` column heading just after the **Price** column. Then add a `<td>` column near the end of the template to render the `@item.Rating` value. Below is what the updated *Index.cshtml* view template looks like:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.Title)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.ReleaseDate)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Genre)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.Price)
        </th>
         <th>
            @Html.DisplayNameFor(model => model.Rating)
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Rating)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}

</table>
```

Next, open the *\Views\Movies\Create.cshtml* file and add the following markup near the end of the form. This renders a text box so that you can specify a rating when a new movie is created.

```
<div class="editor-label">
    @Html.LabelFor(model => model.Rating)
</div>
<div class="editor-field">
    @Html.EditorFor(model => model.Rating)
    @Html.ValidationMessageFor(model => model.Rating)
</div>
```

You've now updated the application code to support the new `Rating` property.

Now run the application and navigate to the */Movies* URL. When you do this, though, you'll see one of the following errors:

You're seeing this error because the updated `Movie` model class in the application is now different than the schema of the `Movie` table of the existing database. (There's no `Rating` column in the database table.)

There are a few approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient when doing active development on a test database; it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you *don't* want to use this approach on a production database! Using an initializer to automatically seed a database with test data is often a productive way to develope an application. For more information on Entity Framework database initializers, see Tom Dykstra's ASP.NET MVC/Entity Framework tutorial.
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.
3. Use Code First Migrations to update the database schema.

For this tutorial, we'll use Code First Migrations.

Update the Seed method so that it provides a value for the new column. Open Migrations\Configuration.cs file and add a Rating field to each Movie object.

```
new Movie
{
    Title = "When Harry Met Sally",
    ReleaseDate = DateTime.Parse("1989-1-11"),
    Genre = "Romantic Comedy",
    Rating = "G",
    Price = 7.99M
},
```

Build the solution, and then open the **Package Manager Console** window and enter the following command:

`add-migration AddRatingMig`

The `add-migration` command tells the migration framework to examine the current movie model with the current movie DB schema and create the necessary code to migrate the DB to the new model. The AddRatingMig is arbitrary and is used to name the migration file. It's helpful to use a meaningful name for the migration step.

When this command finishes, Visual Studio opens the class file that defines the new `DbMigration` derived class, and in the `Up` method you can see the code that creates the new column.

```
public partial class AddRatingMig : DbMigration
{
    public override void Up()
    {
        AddColumn("dbo.Movies", "Rating", c => c.String());
    }

    public override void Down()
    {
        DropColumn("dbo.Movies", "Rating");
    }
}
```

Build the solution, and then enter the "update-database" command in the **Package Manager Console** window.

The following image shows the output in the **Package Manager Console** window (The date stamp prepending

AddRatingMig will be different.)

```
PM> update-database
Specify the '-Verbose' flag to view the SQL statements being applied to the target database.
Applying code-based migrations: [201207260218501_AddRatingMig].
Applying code-based migration: 201207260218501_AddRatingMig.
Running Seed method.
PM>
```

Re-run the application and navigate to the /Movies URL. You can see the new Rating field.

Click the **Create New** link to add a new movie. Note that you can add a rating.

Click **Create**. The new movie, including the rating, now shows up in the movies listing:

You should also add the `Rating` field to the Edit, Details and SearchIndex view templates.

You could enter the "update-database" command in the **Package Manager Console** window again and no changes would be made, because the schema matches the model.

In this section you saw how you can modify model objects and keep the database in sync with the changes. You also learned a way to populate a newly created database with sample data so you can try out scenarios. Next, let's look at how you can add richer validation logic to the model classes and enable some business rules to be enforced.

Adding Validation to the Model

2/20/2020 • 11 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this section you'll add validation logic to the `Movie` model, and you'll ensure that the validation rules are enforced any time a user attempts to create or edit a movie using the application.

Keeping Things DRY

One of the core design tenets of ASP.NET MVC is DRY ("Don't Repeat Yourself"). ASP.NET MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an application. This reduces the amount of code you need to write and makes the code you do write less error prone and easier to maintain.

The validation support provided by ASP.NET MVC and Entity Framework Code First is a great example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and the rules are enforced everywhere in the application.

Let's look at how you can take advantage of this validation support in the movie application.

Adding Validation Rules to the Movie Model

You'll begin by adding some validation logic to the `Movie` class.

Open the *Movie.cs* file. Add a `using` statement at the top of the file that references the `System.ComponentModel.DataAnnotations` namespace:

```
using System.ComponentModel.DataAnnotations;
```

Notice the namespace does not contain `System.Web`. DataAnnotations provides a built-in set of validation attributes that you can apply declaratively to any class or property.

Now update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, and `Range` validation attributes. Use the following code as an example of where to apply the attributes.

```
public class Movie {
    public int ID { get; set; }

    [Required]
    public string Title { get; set; }

    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Required]
    public string Genre { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

Run the application and you will again get the following run time error:

The model backing the 'MovieDBContext' context has changed since the database was created. Consider using Code First Migrations to update the database (https://go.microsoft.com/fwlink/?LinkId=238269).

We will use migrations to update the schema. Build the solution, and then open the **Package Manager Console** window and enter the following commands:

```
add-migration AddDataAnnotationsMig
update-database
```

When this command finishes, Visual Studio opens the class file that defines the new `DbMigration` derived class with the name specified (*AddDataAnnotationsMig*), and in the `Up` method you can see the code that updates the schema constraints. The `Title` and `Genre` fields are no longer nullable (that is, you must enter a value) and the `Rating` field has a maximum length of 5.

The validation attributes specify behavior that you want to enforce on the model properties they are applied to. The `Required` attribute indicates that a property must have a value; in this sample, a movie has to have values for the `Title`, `ReleaseDate`, `Genre`, and `Price` properties in order to be valid. The `Range` attribute constrains a value to within a specified range. The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length. Intrinsic types (such as `decimal, int, float, DateTime`) are required by default and don't need the `Required` attribute.

Code First ensures that the validation rules you specify on a model class are enforced before the application saves changes in the database. For example, the code below will throw an exception when the `SaveChanges` method is called, because several required `Movie` property values are missing and the price is zero (which is out of the valid range).

```
MovieDBContext db = new MovieDBContext();

Movie movie = new Movie();
movie.Title = "Gone with the Wind";
movie.Price = 0.0M;

db.Movies.Add(movie);
db.SaveChanges();        // <= Will throw server side validation exception
```

Having validation rules automatically enforced by the .NET Framework helps make your application more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Here's a complete code listing for the updated *Movie.cs* file:

```
using System;
using System.Data.Entity;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models {
    public class Movie {
        public int ID { get; set; }

        [Required]
        public string Title { get; set; }

        [DataType(DataType.Date)]
        public DateTime ReleaseDate { get; set; }

        [Required]
        public string Genre { get; set; }

        [Range(1, 100)]
        [DataType(DataType.Currency)]
        public decimal Price { get; set; }

        [StringLength(5)]
        public string Rating { get; set; }
    }

    public class MovieDBContext : DbContext {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

Validation Error UI in ASP.NET MVC

Re-run the application and navigate to the */Movies* URL.

Click the **Create New** link to add a new movie. Fill out the form with some invalid values and then click the **Create** button.

NOTE

to support jQuery validation for non-English locales that use a comma (",") for a decimal point, you must include *globalize.js* and your specific *cultures/globalize.cultures.js* file(from https://github.com/jquery/globalize) and JavaScript to use `Globalize.parseFloat`. The following code shows the modifications to the Views\Movies\Edit.cshtml file to work with the "fr-FR" culture:

```
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
    <script src="~/Scripts/globalize.js"></script>
    <script src="~/Scripts/globalize.culture.fr-FR.js"></script>
    <script>
        $.validator.methods.number = function (value, element) {
            return this.optional(element) ||
                !isNaN(Globalize.parseFloat(value));
        }
        $(document).ready(function () {
            Globalize.culture('fr-FR');
        });
    </script>
    <script>
        jQuery.extend(jQuery.validator.methods, {
            range: function (value, element, param) {
                //Use the Globalization plugin to parse the value
                var val = $.global.parseFloat(value);
                return this.optional(element) || (
                    val >= param[0] && val <= param[1]);
            }
        });

    </script>
}
```

Notice how the form has automatically used a red border color to highlight the text boxes that contain invalid data and has emitted an appropriate validation error message next to each one. The errors are enforced both client-side (using JavaScript and jQuery) and server-side (in case a user has JavaScript disabled).

A real benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.cshtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified by using validation attributes on the properties of the `Movie` model class.

You might have noticed for the properties `Title` and `Genre`, the required attribute is not enforced until you submit the form (hit the **Create** button), or enter text into the input field and removed it. For a field which is initially empty (such as the fields on the Create view) and which has only the required attribute and no other validation attributes, you can do the following to trigger validation:

1. Tab into the field.
2. Enter some text.
3. Tab out.
4. Tab back into the field.
5. Remove the text.
6. Tab out.

The above sequence will trigger the required validation without hitting the submit button. Simply hitting the submit button without entering any of the fields will trigger client side validation. The form data is not sent to the server until there are no client side validation errors. You can test this by putting a break point in the HTTP Post method or using the fiddler tool or the IE 9 F12 developer tools.

How Validation Occurs in the Create View and Create Action Method

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The next listing shows what the `Create` methods in the `MovieController` class look like. They're unchanged from how you created them earlier in this tutorial.

```
//
// GET: /Movies/Create

public ActionResult Create()
{
    return View();
}

//
// POST: /Movies/Create

[HttpPost]
public ActionResult Create(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Movies.Add(movie);
        db.SaveChanges();
        return RedirectToAction("Index");
    }

    return View(movie);
}
```

The first (HTTP GET) `Create` action method displays the initial Create form. The second (`[HttpPost]`) version handles the form post. The second `Create` method (The `HttpPost` version) calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method re-displays the form. If there are no errors, the method saves the new movie in the database. In our movie example we are using, **the form is not posted to the server when their are validation errors detected on the client side; the second `Create` method is never called**. If you disable JavaScript in your browser, client validation is disabled and the HTTP POST `Create` method calls `ModelState.IsValid` to check whether the movie has any validation errors.

You can set a break point in the `HttpPost Create` method and verify the method is never called, client side validation will not submit the form data when validation errors are detected. If you disable JavaScript in your browser, then submit the form with errors, the break point will be hit. You still get full validation without JavaScript. The following image shows how to disable JavaScript in Internet Explorer.

```
[HttpPost]
public ActionResult Create(Movie movie)
{
    if (ModelState.IsValid)
    {                                   ModelState.IsValid | false
        db.Movies.Add(movie);
        db.SaveChanges();
        return RedirectToAction("Index");
    }

    return View(movie);
}
```

The following image shows how to disable JavaScript in the FireFox browser.

The following image shows how to disable JavaScript with the Chrome browser.

Below is the *Create.cshtml* view template that you scaffolded earlier in the tutorial. It's used by the action methods shown above both to display the initial form and to redisplay it in the event of an error.

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Create";
}

<h2>Create</h2>

<script src="@Url.Content("~/Scripts/jquery.validate.min.js")"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")"></script>

@using (Html.BeginForm()) {
    @Html.ValidationSummary(true)

    <fieldset>
        <legend>Movie</legend>

        <div class="editor-label">
            @Html.LabelFor(model => model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Title)
            @Html.ValidationMessageFor(model => model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.ReleaseDate)
            @Html.ValidationMessageFor(model => model.ReleaseDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Genre)
            @Html.ValidationMessageFor(model => model.Genre)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Price)
            @Html.ValidationMessageFor(model => model.Price)
        </div>
        <div class="editor-label">
    @Html.LabelFor(model => model.Rating)
</div>
<div class="editor-field">
    @Html.EditorFor(model => model.Rating)
    @Html.ValidationMessageFor(model => model.Rating)
</div>
        <p>
            <input type="submit" value="Create" />
        </p>
    </fieldset>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Notice how the code uses an `Html.EditorFor` helper to output the `<input>` element for each `Movie` property.

Next to this helper is a call to the `Html.ValidationMessageFor` helper method. These two helper methods work with the model object that's passed by the controller to the view (in this case, a `Movie` object). They automatically look for validation attributes specified on the model and display error messages as appropriate.

What's really nice about this approach is that neither the controller nor the Create view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class. These same validation rules are automatically applied to the Edit view and any other views templates you might create that edit your model.

If you want to change the validation logic later, you can do so in exactly one place by adding validation attributes to the model (in this example, the `movie` class). You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Adding Formatting to the Movie Model

Open the *Movie.cs* file and examine the `Movie` class. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. We've already applied a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DisplayFormat` attribute.

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

The `DataType` attributes are not validation attributes, they are used to tell the view engine how to render the HTML. In the example above, the `DataType.Date` attribute displays the movie dates as dates only, without time. For example, the following `DataType` attributes don't validate the format of the data:

```
[DataType(DataType.EmailAddress)]
[DataType(DataType.PhoneNumber)]
[DataType(DataType.Url)]
```

The attributes listed above only provide hints for the view engine to format the data (and supply attributes such as <a> for URL's and <a href="mailto:EmailAddress.com"> for email. You can use the RegularExpression attribute to validate the format of the data.

An alternative approach to using the `DataType` attributes, you could explicitly set a `DataFormatString` value. The following code shows the release date property with a date format string (namely, "d"). You'd use this to specify that you don't want to time as part of the release date.

```
[DisplayFormat(DataFormatString = "{0:d}")]
public DateTime ReleaseDate { get; set; }
```

The complete `Movie` class is shown below.

```
public class Movie {
    public int ID { get; set; }

    [Required]
    public string Title { get; set; }

    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Required]
    public string Genre { get; set; }

    [Range(1, 100)]
    [DataType(DataType.Currency)]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

Run the application and browse to the `Movies` controller. The release date and price are nicely formatted. The image below shows the release date and price using "fr-FR" as the culture.

The image below shows the same data displayed with the default culture (English US).

In the next part of the series, we'll review the application and make some improvements to the automatically generated `Details` and `Delete` methods.

PREVIOUS NEXT

Examining the Details and Delete Methods

2/20/2020 • 4 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

In this part of the tutorial, you'll examine the automatically generated `Details` and `Delete` methods.

Examining the Details and Delete Methods

Open the `Movie` controller and examine the `Details` method.

```
public ActionResult Details(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

The MVC scaffolding engine that created this action method adds a comment showing a HTTP request that invokes the method. In this case it's a `GET` request with three URL segments, the `Movies` controller, the `Details` method and a `ID` value.

Code First makes it easy to search for data using the `Find` method. An important security feature built into the method is that the code verifies that the `Find` method has found a movie before the code tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:xxxx/Movies/Details/1` to something like `http://localhost:xxxx/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you did not check for a null movie, a null movie would result in a database error.

Examine the `Delete` and `DeleteConfirmed` methods.

```
// GET: /Movies/Delete/5
public ActionResult Delete(int? id)
{
    if (id == null)
    {
        return new HttpStatusCodeResult(HttpStatusCode.BadRequest);
    }
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}

// POST: /Movies/Delete/5
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public ActionResult DeleteConfirmed(int id)
{
    Movie movie = db.Movies.Find(id);
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Note that the `HTTP Get``Delete` method doesn't delete the specified movie, it returns a view of the movie where you can submit (`HttpPost`) the deletion.. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole. For more information about this, see Stephen Walther's blog entry ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes.

The `HttpPost` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique

signature or name. The two method signatures are shown below:

```
// GET: /Movies/Delete/5
public ActionResult Delete(int? id)

//
// POST: /Movies/Delete/5
[HttpPost, ActionName("Delete")]
public ActionResult DeleteConfirmed(int id)
```

The common language runtime (CLR) requires overloaded methods to have a unique parameter signature (same method name but different list of parameters). However, here you need two Delete methods -- one for GET and one for POST -- that both have the same parameter signature. (They both need to accept a single integer as a parameter.)

To sort this out, you can do a couple of things. One is to give the methods different names. That's what the scaffolding mechanism did in the preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. This effectively performs mapping for the routing system so that a URL that includes */Delete/* for a POST request will find the `DeleteConfirmed` method.

Another common way to avoid a problem with methods that have identical names and signatures is to artificially change the signature of the POST method to include an unused parameter. For example, some developers add a parameter type `FormCollection` that is passed to the POST method, and then simply don't use the parameter:

```
public ActionResult Delete(FormCollection fcNotUsed, int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Summary

You now have a complete ASP.NET MVC application that stores data in a local DB database. You can create, read, update, delete, and search for movies.

Next Steps

After you have built and tested a web application, the next step is to make it available to other people to use over the Internet. To do that, you have to deploy it to a web hosting provider. Microsoft offers free web hosting for up to 10 web sites in a free Windows Azure trial account. I suggest you next follow my tutorial Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL Database to a Windows Azure Web Site. An excellent tutorial is Tom Dykstra's intermediate-level Creating an Entity Framework Data Model for an ASP.NET MVC Application. Stackoverflow and the ASP.NET MVC forums are a great places to ask questions. Follow me on twitter so you can get updates on my latest tutorials.

Feedback is welcome.

Creating an Entity Framework Data Model for an ASP.NET MVC Application (1 of 10)

2/20/2020 • 23 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

> **NOTE**
>
> A newer version of this tutorial series is available, for Visual Studio 2013, Entity Framework 6, and MVC 5.

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 and Visual Studio 2012. The sample application is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This tutorial series explains how to build the Contoso University sample application. You can download the completed application.

Code First

There are three ways you can work with data in the Entity Framework: *Database First*, *Model First*, and *Code First*. This tutorial is for Code First. For information about the differences between these workflows and guidance on how to choose the best one for your scenario, see Entity Framework Development Workflows.

MVC

The sample application is built on ASP.NET MVC. If you prefer to work with the ASP.NET Web Forms model, see the Model Binding and Web Forms tutorial series and ASP.NET Data Access Content Map.

Software versions

SHOWN IN THE TUTORIAL	ALSO WORKS WITH
Windows 8	Windows 7
Visual Studio 2012	Visual Studio 2012 Express for Web. This is automatically installed by the Windows Azure SDK if you don't already have VS 2012 or VS 2012 Express for Web. Visual Studio 2013 should work, but the tutorial has not been tested with it, and some menu selections and dialog boxes are different. The VS 2013 version of the Windows Azure SDK is required for Windows Azure deployment.
.NET 4.5	Most of the features shown will work in .NET 4, but some won't. For example, enum support in EF requires .NET 4.5.
Entity Framework 5	

SHOWN IN THE TUTORIAL	ALSO WORKS WITH
Windows Azure SDK 2.1	If you skip the Windows Azure deployment steps, you don't need the SDK. When a new version of the SDK is released, the link will install the newer version. In that case, you might have to adapt some of the instructions to new UI and features.

Questions

If you have questions that are not directly related to the tutorial, you can post them to the ASP.NET Entity Framework forum, the Entity Framework and LINQ to Entities forum, or StackOverflow.com.

Acknowledgments

See the last tutorial in the series for acknowledgments and a note about VB.

Original version of the tutorial

The original version of the tutorial is available in the EF 4.1 / MVC 3 e-book.

The Contoso University Web Application

The application you'll be building in these tutorials is a simple university web site.

Users can view and update student, course, and instructor information. Here are a few of the screens you'll create.

© 2013 - Contoso University

The UI style of this site has been kept close to what's generated by the built-in templates, so that the tutorial can focus mainly on how to use the Entity Framework.

Prerequisites

The directions and screen shots in this tutorial assume that you're using Visual Studio 2012 or Visual Studio 2012 Express for Web, with the latest update and Azure SDK for .NET installed as of July, 2013. You can get all of this with the following link:

Azure SDK for .NET (Visual Studio 2012)

If you have Visual Studio installed, the link above will install any missing components. If you don't have Visual Studio, the link will install Visual Studio 2012 Express for Web. You can use Visual Studio 2013, but some of the required procedures and screens will differ.

Create an MVC Web Application

Open Visual Studio and create a new C# project named "ContosoUniversity" using the **ASP.NET MVC 4 Web Application** template. Make sure you target **.NET Framework 4.5** (you'll be using `enum` properties, and that requires .NET 4.5).

In the **New ASP.NET MVC 4 Project** dialog box select the **Internet Application** template.

Leave the **Razor** view engine selected, and leave the **Create a unit test project** check box cleared.

Click **OK**.

Set Up the Site Style

A few simple changes will set up the site menu, layout, and home page.

Open *Views\Shared_Layout.cshtml*, and replace the contents of the file with the following code. The changes are highlighted.

```
<!DOCTYPE html>
<html lang="en">
    <head>
        <meta charset="utf-8" />
        <title>@ViewBag.Title - Contoso University</title>
        <link href="~/favicon.ico" rel="shortcut icon" type="image/x-icon" />
        <meta name="viewport" content="width=device-width" />
        @Styles.Render("~/Content/css")
        @Scripts.Render("~/bundles/modernizr")
    </head>
    <body>
        <header>
            <div class="content-wrapper">
                <div class="float-left">
                    <p class="site-title">@Html.ActionLink("Contoso University", "Index", "Home")</p>
                </div>
                <div class="float-right">
                    <section id="login">
                        @Html.Partial("_LoginPartial")
                    </section>
                    <nav>
                        <ul id="menu">
                            <li>@Html.ActionLink("Home", "Index", "Home")</li>
                            <li>@Html.ActionLink("About", "About", "Home")</li>
                            <li>@Html.ActionLink("Students", "Index", "Student")</li>
                            <li>@Html.ActionLink("Courses", "Index", "Course")</li>
                            <li>@Html.ActionLink("Instructors", "Index", "Instructor")</li>
                            <li>@Html.ActionLink("Departments", "Index", "Department")</li>
                        </ul>
                    </nav>
                </div>
            </div>
        </header>
        <div id="body">
            @RenderSection("featured", required: false)
            <section class="content-wrapper main-content clear-fix">
                @RenderBody()
            </section>
        </div>
        <footer>
            <div class="content-wrapper">
                <div class="float-left">
                    <p>&copy; @DateTime.Now.Year - Contoso University</p>
                </div>
            </div>
        </footer>

        @Scripts.Render("~/bundles/jquery")
        @RenderSection("scripts", required: false)
    </body>
</html>
```

This code makes the following changes:

- Replaces the template instances of "My ASP.NET MVC Application" and "your logo here" with "Contoso University".
- Adds several action links that will be used later in the tutorial.

In *Views\Home\Index.cshtml*, replace the contents of the file with the following code to eliminate the template paragraphs about ASP.NET and MVC:

```
@{
    ViewBag.Title = "Home Page";
}
@section featured {
    <section class="featured">
        <div class="content-wrapper">
            <hgroup class="title">
                <h1>@ViewBag.Title.</h1>
                <h2>@ViewBag.Message</h2>
            </hgroup>
        </div>
    </section>
}
```

In *Controllers\HomeController.cs*, change the value for `ViewBag.Message` in the `Index` Action method to "Welcome to Contoso University!", as shown in the following example:

```
public ActionResult Index()
{
    ViewBag.Message = "Welcome to Contoso University";

    return View();
}
```

Press CTRL+F5 to run the site. You see the home page with the main menu.

Create the Data Model

Next you'll create entity classes for the Contoso University application. You'll start with the following three entities:

There's a one-to-many relationship between `Student` and `Enrollment` entities, and there's a one-to-many relationship between `Course` and `Enrollment` entities. In other words, a student can be enrolled in any number of courses, and a course can have any number of students enrolled in it.

In the following sections you'll create a class for each one of these entities.

> **NOTE**
>
> If you try to compile the project before you finish creating all of these entity classes, you'll get compiler errors.

The Student Entity

In the *Models* folder, create *Student.cs* and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int StudentID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `StudentID` property will become the primary key column of the database table that corresponds to this class. By default, the Entity Framework interprets a property that's named `ID` or *classname* `ID` as the primary key.

The `Enrollments` property is a *navigation property*. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity will hold all of the `Enrollment` entities that are related to that `Student` entity. In other words, if a given `Student` row in the database has two related `Enrollment` rows (rows that contain that student's primary key value in their `StudentID` foreign key column), that `Student` entity's `Enrollments` navigation property will contain those two `Enrollment` entities.

Navigation properties are typically defined as `virtual` so that they can take advantage of certain Entity Framework functionality such as *lazy loading*. (Lazy loading will be explained later, in the Reading Related Data tutorial later in this series.

If a navigation property can hold multiple entities (as in many-to-many or one-to-many relationships), its type must be a list in which entries can be added, deleted, and updated, such as `ICollection`.

The Enrollment Entity

In the *Models* folder, create *Enrollment.cs* and replace the existing code with the following code:

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public virtual Course Course { get; set; }
        public virtual Student Student { get; set; }
    }
}
```

The Grade property is an enum. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade — null means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity (unlike the `Student.Enrollments` navigation property you saw earlier, which can hold multiple `Enrollment` entities).

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

The Course Entity

In the *Models* folder, create *Course.cs*, replacing the existing code with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

We'll say more about the [DatabaseGenerated(DatabaseGeneratedOption.None)] attribute in the next tutorial. Basically, this attribute lets you enter the primary key for the course rather than having the database generate it.

Create the Database Context

The main class that coordinates Entity Framework functionality for a given data model is the *database context* class. You create this class by deriving from the System.Data.Entity.DbContext class. In your code you specify which entities are included in the data model. You can also customize certain Entity Framework behavior. In this project, the class is named `SchoolContext`.

Create a folder named *DAL* (for Data Access Layer). In that folder create a new class file named *SchoolContext.cs*, and replace the existing code with the following code:

```
using ContosoUniversity.Models;
using System.Data.Entity;
using System.Data.Entity.ModelConfiguration.Conventions;

namespace ContosoUniversity.DAL
{
    public class SchoolContext : DbContext
    {
        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(DbModelBuilder modelBuilder)
        {
            modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();
        }
    }
}
```

This code creates a DbSet property for each entity set. In Entity Framework terminology, an *entity set* typically corresponds to a database table, and an *entity* corresponds to a row in the table.

The `modelBuilder.Conventions.Remove` statement in the OnModelCreating method prevents table names from being pluralized. If you didn't do this, the generated tables would be named `Students`, `Courses`, and `Enrollments`. Instead, the table names will be `Student`, `Course`, and `Enrollment`. Developers disagree about whether table names should be pluralized or not. This tutorial uses the singular form, but the important point is

that you can select whichever form you prefer by including or omitting this line of code.

SQL Server Express LocalDB

LocalDB is a lightweight version of the SQL Server Express Database Engine that starts on demand and runs in user mode. LocalDB runs in a special execution mode of SQL Server Express that enables you to work with databases as *.mdf* files. Typically, LocalDB database files are kept in the *App_Data* folder of a web project. The user instance feature in SQL Server Express also enables you to work with *.mdf* files, but the user instance feature is deprecated; therefore, LocalDB is recommended for working with *.mdf* files.

Typically SQL Server Express is not used for production web applications. LocalDB in particular is not recommended for production use with a web application because it is not designed to work with IIS.

In Visual Studio 2012 and later versions, LocalDB is installed by default with Visual Studio. In Visual Studio 2010 and earlier versions, SQL Server Express (without LocalDB) is installed by default with Visual Studio; you have to install it manually if you're using Visual Studio 2010.

In this tutorial you'll work with LocalDB so that the database can be stored in the *App_Data* folder as an *.mdf* file. Open the root *Web.config* file and add a new connection string to the `connectionStrings` collection, as shown in the following example. (Make sure you update the *Web.config* file in the root project folder. There's also a *Web.config* file is in the *Views* subfolder that you don't need to update.)

```
<add name="SchoolContext" connectionString="Data Source=(LocalDb)\v11.0;Initial
Catalog=ContosoUniversity;Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\ContosoUniversity.mdf"
providerName="System.Data.SqlClient" />
```

By default, the Entity Framework looks for a connection string named the same as the `DbContext` class (`SchoolContext` for this project). The connection string you've added specifies a LocalDB database named *ContosoUniversity.mdf* located in the *App_Data* folder. For more information, see SQL Server Connection Strings for ASP.NET Web Applications.

You don't actually need to specify the connection string. If you don't supply a connection string, Entity Framework will create one for you; however, the database might not be in the *App_data* folder of your app. For information on where the database will be created, see Code First to a New Database.

The `connectionStrings` collection also has a connection string named `DefaultConnection` which is used for the membership database. You won't be using the membership database in this tutorial. The only difference between the two connection strings is the database name and the name attribute value.

Set up and Execute a Code First Migration

When you first start to develop an application, your data model changes frequently, and each time the model changes it gets out of sync with the database. You can configure the Entity Framework to automatically drop and re-create the database each time you change the data model. This is not a problem early in development because test data is easily re-created, but after you have deployed to production you usually want to update the database schema without dropping the database. The Migrations feature enables Code First to update the database without dropping and re-creating it. Early in the development cycle of a new project you might want to use DropCreateDatabaseIfModelChanges to drop, recreate and re-seed the database each time the model changes. One you get ready to deploy your application, you can convert to the migrations approach. For this tutorial you'll only use migrations. For more information, see Code First Migrations and Migrations Screencast Series.

Enable Code First Migrations

1. From the **Tools** menu, click **NuGet Package Manager** and then **Package Manager Console**.

2. At the `PM>` prompt enter the following command:

```
enable-migrations -contexttypename SchoolContext
```

This command creates a *Migrations* folder in the ContosoUniversity project, and it puts in that folder a *Configuration.cs* file that you can edit to configure Migrations.

The `Configuration` class includes a `Seed` method that is called when the database is created and every time it is updated after a data model change.

```
internal sealed class Configuration :
DbMigrationsConfiguration<ContosoUniversity.Models.SchoolContext>
{
    public Configuration()
    {
        AutomaticMigrationsEnabled = false;
    }

    protected override void Seed(ContosoUniversity.Models.SchoolContext context)
    {
        //  This method will be called after migrating to the latest version.

        //  You can use the DbSet<T>.AddOrUpdate() helper extension method
        //  to avoid creating duplicate seed data. E.g.
        //
        //    context.People.AddOrUpdate(
        //      p => p.FullName,
        //      new Person { FullName = "Andrew Peters" },
        //      new Person { FullName = "Brice Lambson" },
        //      new Person { FullName = "Rowan Miller" }
        //    );
        //
    }
}
```

The purpose of this `Seed` method is to enable you to insert test data into the database after Code First creates it or updates it.

Set up the Seed Method

The Seed method runs when Code First Migrations creates the database and every time it updates the database to the latest migration. The purpose of the Seed method is to enable you to insert data into your tables before the application accesses the database for the first time.

In earlier versions of Code First, before Migrations was released, it was common for `Seed` methods to insert test data, because with every model change during development the database had to be completely deleted and re-created from scratch. With Code First Migrations, test data is retained after database changes, so including test data in the Seed method is typically not necessary. In fact, you don't want the `Seed` method to insert test data if you'll be using Migrations to deploy the database to production, because the `Seed` method will run in production. In that case you want the `Seed` method to insert into the database only the data that you want to be inserted in production. For example, you might want the database to include actual department names in the `Department` table when the application becomes available in production.

For this tutorial, you'll be using Migrations for deployment, but your `Seed` method will insert test data anyway in order to make it easier to see how application functionality works without having to manually insert a lot of data.

1. Replace the contents of the *Configuration.cs* file with the following code, which will load test data into the new database.

```
namespace ContosoUniversity.Migrations
{
   using System;
   using System.Collections.Generic;
   using System.Data.Entity.Migrations;
   using System.Linq;
   using ContosoUniversity.Models;

   internal sealed class Configuration :
DbMigrationsConfiguration<ContosoUniversity.DAL.SchoolContext>
   {
      public Configuration()
      {
```

```
            AutomaticMigrationsEnabled = false;
        }

        protected override void Seed(ContosoUniversity.DAL.SchoolContext context)
        {
            var students = new List<Student>
                {
                    new Student { FirstMidName = "Carson",   LastName = "Alexander",
                        EnrollmentDate = DateTime.Parse("2010-09-01") },
                    new Student { FirstMidName = "Meredith", LastName = "Alonso",
                        EnrollmentDate = DateTime.Parse("2012-09-01") },
                    new Student { FirstMidName = "Arturo",   LastName = "Anand",
                        EnrollmentDate = DateTime.Parse("2013-09-01") },
                    new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                        EnrollmentDate = DateTime.Parse("2012-09-01") },
                    new Student { FirstMidName = "Yan",      LastName = "Li",
                        EnrollmentDate = DateTime.Parse("2012-09-01") },
                    new Student { FirstMidName = "Peggy",    LastName = "Justice",
                        EnrollmentDate = DateTime.Parse("2011-09-01") },
                    new Student { FirstMidName = "Laura",    LastName = "Norman",
                        EnrollmentDate = DateTime.Parse("2013-09-01") },
                    new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                        EnrollmentDate = DateTime.Parse("2005-08-11") }
                };
            students.ForEach(s => context.Students.AddOrUpdate(p => p.LastName, s));
            context.SaveChanges();

            var courses = new List<Course>
                {
                    new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3, },
                    new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3, },
                    new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3, },
                    new Course {CourseID = 1045, Title = "Calculus",       Credits = 4, },
                    new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4, },
                    new Course {CourseID = 2021, Title = "Composition",    Credits = 3, },
                    new Course {CourseID = 2042, Title = "Literature",     Credits = 4, }
                };
            courses.ForEach(s => context.Courses.AddOrUpdate(p => p.Title, s));
            context.SaveChanges();

            var enrollments = new List<Enrollment>
                {
                    new Enrollment {
                        StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                        CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
                        Grade = Grade.A
                    },
                     new Enrollment {
                        StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                        CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
                        Grade = Grade.C
                     },
                     new Enrollment {
                        StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                        CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
                        Grade = Grade.B
                     },
                     new Enrollment {
                         StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
                        CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
                        Grade = Grade.B
                     },
                     new Enrollment {
                         StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
                        CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
                        Grade = Grade.B
                     },
                     new Enrollment {
                        StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
```

```
                    CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Anand").StudentID,
                    CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Anand").StudentID,
                    CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
                    Grade = Grade.B
                 },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Barzdukas").StudentID,
                    CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").StudentID,
                    CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                    Grade = Grade.B
                 },
                 new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Justice").StudentID,
                    CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                    Grade = Grade.B
                 }
             };

          foreach (Enrollment e in enrollments)
          {
             var enrollmentInDataBase = context.Enrollments.Where(
                 s =>
                      s.Student.StudentID == e.StudentID &&
                      s.Course.CourseID == e.CourseID).SingleOrDefault();
             if (enrollmentInDataBase == null)
             {
                context.Enrollments.Add(e);
             }
          }
          context.SaveChanges();
       }
    }
 }
```

The Seed method takes the database context object as an input parameter, and the code in the method uses that object to add new entities to the database. For each entity type, the code creates a collection of new entities, adds them to the appropriate DbSet property, and then saves the changes to the database. It isn't necessary to call the SaveChanges method after each group of entities, as is done here, but doing that helps you locate the source of a problem if an exception occurs while the code is writing to the database.

Some of the statements that insert data use the AddOrUpdate method to perform an "upsert" operation. Because the `Seed` method runs with every migration, you can't just insert data, because the rows you are trying to add will already be there after the first migration that creates the database. The "upsert" operation prevents errors that would happen if you try to insert a row that already exists, but it ***overrides*** any changes to data that you may have made while testing the application. With test data in some tables you might not want that to happen: in some cases when you change data while testing you want your changes to remain after database updates. In that case you want to do a conditional insert operation: insert a row only if it doesn't already exist. The Seed method uses both approaches.

The first parameter passed to the AddOrUpdate method specifies the property to use to check if a row already exists. For the test student data that you are providing, the `LastName` property can be used for this purpose since each last name in the list is unique:

```
context.Students.AddOrUpdate(p => p.LastName, s)
```

This code assumes that last names are unique. If you manually add a student with a duplicate last name, you'll get the following exception the next time you perform a migration.

Sequence contains more than one element

For more information about the `AddOrUpdate` method, see Take care with EF 4.3 AddOrUpdate Method on Julie Lerman's blog.

The code that adds `Enrollment` entities doesn't use the `AddOrUpdate` method. It checks if an entity already exists and inserts the entity if it doesn't exist. This approach will preserve changes you make to an enrollment grade when migrations run. The code loops through each member of the `Enrollment` List and if the enrollment is not found in the database, it adds the enrollment to the database. The first time you update the database, the database will be empty, so it will add each enrollment.

```
foreach (Enrollment e in enrollments)
{
    var enrollmentInDataBase = context.Enrollments.Where(
        s => s.Student.StudentID == e.Student.StudentID &&
             s.Course.CourseID == e.Course.CourseID).SingleOrDefault();
    if (enrollmentInDataBase == null)
    {
        context.Enrollments.Add(e);
    }
}
```

For information about how to debug the `Seed` method and how to handle redundant data such as two students named "Alexander Carson", see Seeding and Debugging Entity Framework (EF) DBs on Rick Anderson's blog.

2. Build the project.

Create and Execute the First Migration

1. In the Package Manager Console window, enter the following commands:

```
add-migration InitialCreate
update-database
```

The `add-migration` command adds to the Migrations folder a *[DateStamp]_InitialCreate.cs* file that contains code which creates the database. The first parameter (`InitialCreate)` is used for the file name and can be whatever you want; you typically choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them. Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method. The following code shows the contents of the `InitialCreate` file:

```
namespace ContosoUniversity.Migrations
{
    using System;
    using System.Data.Entity.Migrations;

    public partial class InitialCreate : DbMigration
    {
        public override void Up()
        {
            CreateTable(
                "dbo.Student",
                c => new
                    {
                        StudentID = c.Int(nullable: false, identity: true),
                        LastName = c.String(),
                        FirstMidName = c.String(),
                        EnrollmentDate = c.DateTime(nullable: false),
                    })
                .PrimaryKey(t => t.StudentID);

            CreateTable(
                "dbo.Enrollment",
                c => new
                    {
                        EnrollmentID = c.Int(nullable: false, identity: true),
                        CourseID = c.Int(nullable: false),
                        StudentID = c.Int(nullable: false),
                        Grade = c.Int(),
                    })
                .PrimaryKey(t => t.EnrollmentID)
                .ForeignKey("dbo.Course", t => t.CourseID, cascadeDelete: true)
                .ForeignKey("dbo.Student", t => t.StudentID, cascadeDelete: true)
                .Index(t => t.CourseID)
                .Index(t => t.StudentID);

            CreateTable(
                "dbo.Course",
                c => new
                    {
                        CourseID = c.Int(nullable: false),
                        Title = c.String(),
                        Credits = c.Int(nullable: false),
                    })
                .PrimaryKey(t => t.CourseID);

        }

        public override void Down()
        {
            DropIndex("dbo.Enrollment", new[] { "StudentID" });
            DropIndex("dbo.Enrollment", new[] { "CourseID" });
            DropForeignKey("dbo.Enrollment", "StudentID", "dbo.Student");
            DropForeignKey("dbo.Enrollment", "CourseID", "dbo.Course");
            DropTable("dbo.Course");
            DropTable("dbo.Enrollment");
            DropTable("dbo.Student");
        }
    }
}
```

The `update-database` command runs the `Up` method to create the database and then it runs the `Seed` method to populate the database.

A SQL Server database has now been created for your data model. The name of the database is *ContosoUniversity*, and the *.mdf* file is in your project's *App_Data* folder because that's what you specified in your

connection string.

You can use either **Server Explorer** or **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio. For this tutorial you'll use **Server Explorer**. In Visual Studio Express 2012 for Web, **Server Explorer** is called **Database Explorer**.

1. From the **View** menu, click **Server Explorer**.

2. Click the **Add Connection** icon.

3. If you are prompted with the **Choose Data Source** dialog, click **Microsoft SQL Server**, and then click **Continue**.

4. In the **Add Connection** dialog box, enter **(localdb)\v11.0** for the **Server Name**. Under **Select or enter a database name**, select **ContosoUniversity**.

5. Click **OK**.

6. Expand **SchoolContext** and then expand **Tables**.

7. Right-click the **Student** table and click **Show Table Data** to see the columns that were created and the rows that were inserted into the table.

Creating a Student Controller and Views

The next step is to create an ASP.NET MVC controller and views in your application that can work with one of these tables.

1. To create a `Student` controller, right-click the **Controllers** folder in **Solution Explorer**, select **Add**, and then click **Controller**. In the **Add Controller** dialog box, make the following selections and then click **Add**:

   - Controller name: **StudentController**.
   - Template: **MVC controller with read/write actions and views, using Entity Framework**.
   - Model class: **Student (ContosoUniversity.Models)**. (If you don't see this option in the drop-down list, build the project and try again.)
   - Data context class: **SchoolContext (ContosoUniversity.Models)**.
   - Views: **Razor (CSHTML)**. (The default.)

2. Visual Studio opens the *Controllers\StudentController.cs* file. You see a class variable has been created that instantiates a database context object:

```
private SchoolContext db = new SchoolContext();
```

The `Index` action method gets a list of students from the *Students* entity set by reading the `Students` property of the database context instance:

```
public ViewResult Index()
{
    return View(db.Students.ToList());
}
```

The *Student\Index.cshtml* view displays this list in a table:

```
<table>
    <tr>
        <th>
            @Html.DisplayNameFor(model => model.LastName)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.FirstMidName)
        </th>
        <th>
            @Html.DisplayNameFor(model => model.EnrollmentDate)
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.LastName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.FirstMidName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.StudentID }) |
            @Html.ActionLink("Details", "Details", new { id=item.StudentID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.StudentID })
        </td>
    </tr>
}
```

3. Press CTRL+F5 to run the project.

   Click the **Students** tab to see the test data that the `Seed` method inserted.

Conventions

The amount of code you had to write in order for the Entity Framework to be able to create a complete database for you is minimal because of the use of *conventions*, or assumptions that the Entity Framework makes. Some of them have already been noted:

- The pluralized forms of entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named `ID` or *classname* `ID` are recognized as primary key properties.

You've seen that conventions can be overridden (for example, you specified that table names shouldn't be pluralized), and you'll learn more about conventions and how to override them in the Creating a More Complex Data Model tutorial later in this series. For more information, see Code First Conventions.

Summary

You've now created a simple application that uses the Entity Framework and SQL Server Express to store and display data. In the following tutorial you'll learn how to perform basic CRUD (create, read, update, delete) operations. You can leave feedback at the bottom of this page. Please let us know how you liked this portion of the tutorial and how we could improve it.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

NEXT

Implementing Basic CRUD Functionality with the Entity Framework in ASP.NET MVC Application (2 of 10)

2/20/2020 • 14 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you created an MVC application that stores and displays data using the Entity Framework and SQL Server LocalDB. In this tutorial you'll review and customize the CRUD (create, read, update, delete) code that the MVC scaffolding automatically creates for you in controllers and views.

> **NOTE**
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple, you won't implement a repository until a later tutorial in this series.

In this tutorial, you'll create the following web pages:

Details - Contoso Universi

Creating a Details Page

The scaffolded code for the Students `Index` page left out the `Enrollments` property, because that property holds a collection. In the `Details` page you'll display the contents of the collection in an HTML table.

In *Controllers\StudentController.cs*, the action method for the `Details` view uses the `Find` method to retrieve a single `Student` entity.

```
public ActionResult Details(int id = 0)
{
    Student student = db.Students.Find(id);
    if (student == null)
    {
        return HttpNotFound();
    }
    return View(student);
}
```

The key value is passed to the method as the `id` parameter and comes from route data in the **Details** hyperlink on the Index page.

1. Open *Views\Student\Details.cshtml*. Each field is displayed using a `DisplayFor` helper, as shown in the following example:

```
<div class="display-label">
         @Html.DisplayNameFor(model => model.LastName)
    </div>
    <div class="display-field">
        @Html.DisplayFor(model => model.LastName)
    </div>
```

2. After the `EnrollmentDate` field and immediately before the closing `fieldset` tag, add code to display a list of enrollments, as shown in the following example:

```
<div class="display-label">
        @Html.LabelFor(model => model.Enrollments)
    </div>
    <div class="display-field">
        <table>
            <tr>
                <th>Course Title</th>
                <th>Grade</th>
            </tr>
            @foreach (var item in Model.Enrollments)
            {
                <tr>
                    <td>
                        @Html.DisplayFor(modelItem => item.Course.Title)
                    </td>
                    <td>
                        @Html.DisplayFor(modelItem => item.Grade)
                    </td>
                </tr>
            }
        </table>
    </div>
</fieldset>
<p>
    @Html.ActionLink("Edit", "Edit", new { id=Model.StudentID }) |
    @Html.ActionLink("Back to List", "Index")
</p>
```

This code loops through the entities in the `Enrollments` navigation property. For each `Enrollment` entity in the property, it displays the course title and the grade. The course title is retrieved from the `Course` entity that's stored in the `Course` navigation property of the `Enrollments` entity. All of this data is retrieved from

the database automatically when it's needed. (In other words, you are using lazy loading here. You did not specify *eager loading* for the `Courses` navigation property, so the first time you try to access that property, a query is sent to the database to retrieve the data. You can read more about lazy loading and eager loading in the Reading Related Data tutorial later in this series.)

3. Run the page by selecting the **Students** tab and clicking a **Details** link for Alexander Carson. You see the list of courses and grades for the selected student:

Updating the Create Page

1. In *Controllers\StudentController.cs*, replace the `HttpPost``Create` action method with the following code to add a `try-catch` block and the Bind attribute to the scaffolded method:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create(
   [Bind(Include = "LastName, FirstMidName, EnrollmentDate")]
   Student student)
{
   try
   {
      if (ModelState.IsValid)
      {
         db.Students.Add(student);
         db.SaveChanges();
         return RedirectToAction("Index");
      }
   }
   catch (DataException /* dex */)
   {
      //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.
      ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists see
your system administrator.");
   }
   return View(student);
}
```

This code adds the `Student` entity created by the ASP.NET MVC model binder to the `Students` entity set and then saves the changes to the database. (*Model binder* refers to the ASP.NET MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a `Student` entity for you using property values from the `Form` collection.)

The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery attacks.

```
> [!WARNING]
> Security - The `Bind` attribute is added to protect against *over-posting*. For example, suppose the
`Student` entity includes a `Secret` property that you don't want this web page to update.
>
> [!code-csharp[Main](implementing-basic-crud-functionality-with-the-entity-framework-in-asp-net-mvc-
application/samples/sample5.cs?highlight=7)]
>
> Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as [fiddler]
(http://fiddler2.com/home), or write some JavaScript, to post a `Secret` form value. Without the [Bind]
(https://msdn.microsoft.com/library/system.web.mvc.bindattribute(v=vs.108).aspx) attribute limiting the fields
that the model binder uses when it creates a `Student` instance*,* the model binder would pick up that
`Secret` form value and use it to update the `Student` entity instance. Then whatever value the hacker
specified for the `Secret` form field would be updated in your database. The following image shows the fiddler
tool adding the `Secret` field (with the value "OverPost") to the posted form values.
>
> ![](implementing-basic-crud-functionality-with-the-entity-framework-in-asp-net-mvc-
application/_static/image6.png)
>
> The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although
you never intended that the web page be able to update that property.
>
> It's a security best practice to use the `Include` parameter with the `Bind` attribute to *whitelist*
fields. It's also possible to use the `Exclude` parameter to *blacklist* fields you want to exclude. The
reason `Include` is more secure is that when you add a new property to the entity, the new field is not
automatically protected by an `Exclude` list.
>
> Another alternative approach, and one preferred by many, is to use only view models with model binding. The
view model contains only the properties you want to bind. Once the MVC model binder has finished, you copy the
view model properties to the entity instance.

Other than the `Bind` attribute, the `try-catch` block is the only change you've made to the scaffolded code.
If an exception that derives from [DataException]
(https://msdn.microsoft.com/library/system.data.dataexception.aspx) is caught while the changes are being
saved, a generic error message is displayed. [DataException]
(https://msdn.microsoft.com/library/system.data.dataexception.aspx) exceptions are sometimes caused by
something external to the application rather than a programming error, so the user is advised to try again.
Although not implemented in this sample, a production quality application would log the exception (and non-
null inner exceptions ) with a logging mechanism such as [ELMAH](https://code.google.com/p/elmah/).

The code in *Views\Student\Create.cshtml* is similar to what you saw in *Details.cshtml*, except that
`EditorFor` and `ValidationMessageFor` helpers are used for each field instead of `DisplayFor`. The following
example shows the relevant code:

[!code-cshtml[Main](implementing-basic-crud-functionality-with-the-entity-framework-in-asp-net-mvc-
application/samples/sample6.cshtml)]

*Create.cshtml* also includes `@Html.AntiForgeryToken()`, which works with the `ValidateAntiForgeryToken`
attribute in the controller to help prevent [cross-site request forgery](../../security/xsrfcsrf-prevention-
in-aspnet-mvc-and-web-pages.md) attacks.

No changes are required in *Create.cshtml*.
```

2. Run the page by selecting the **Students** tab and clicking **Create New**.

Some data validation works by default. Enter names and an invalid date and click **Create** to see the error message.

The following highlighted code shows the model validation check.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create(Student student)
{
    if (ModelState.IsValid)
    {
        db.Students.Add(student);
        db.SaveChanges();
        return RedirectToAction("Index");
    }

    return View(student);
}
```

Change the date to a valid value such as 9/1/2005 and click **Create** to see the new student appear in the **Index** page.

Updating the Edit POST Page

In *Controllers\StudentController.cs*, the `HttpGet` `Edit` method (the one without the `HttpPost` attribute) uses the `Find` method to retrieve the selected `Student` entity, as you saw in the `Details` method. You don't need to change this method.

However, replace the `HttpPost` `Edit` action method with the following code to add a `try-catch` block and the Bind attribute:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(
   [Bind(Include = "StudentID, LastName, FirstMidName, EnrollmentDate")]
   Student student)
{
   try
   {
      if (ModelState.IsValid)
      {
         db.Entry(student).State = EntityState.Modified;
         db.SaveChanges();
         return RedirectToAction("Index");
      }
   }
   catch (DataException /* dex */)
   {
      //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
      ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists see your
system administrator.");
   }
   return View(student);
}
```

This code is similar to what you saw in the `HttpPost` `Create` method. However, instead of adding the entity created by the model binder to the entity set, this code sets a flag on the entity indicating it has been changed. When the SaveChanges method is called, the Modified flag causes the Entity Framework to create SQL statements to update the database row. All columns of the database row will be updated, including those that the user didn't change, and concurrency conflicts are ignored. (You'll learn how to handle concurrency in a later tutorial in this series.)

Entity States and the Attach and SaveChanges Methods

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the Add method, that entity's state is set to `Added`. Then when you call the SaveChanges method, the database context issues a SQL `INSERT` command.

An entity may be in one of thefollowing states:

- `Added`. The entity does not yet exist in the database. The `SaveChanges` method must issue an `INSERT` statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.
- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method must issue an `UPDATE` statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method must issue a `DELETE` statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. In a desktop type of application, you read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL `UPDATE` statement that updates only the actual properties that you changed.

The disconnected nature of web apps doesn't allow for this continuous sequence. The DbContext that reads an entity is disposed after a page is rendered. When the `HttpPost` `Edit` action method is called, a new request is made and you have a new instance of the DbContext, so you have to manually set the entity state to `Modified.` Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the

context has no way to know which properties you changed.

If you want the SQL `Update` statement to update only the fields that the user actually changed, you can save the original values in some way (such as hidden fields) so that they are available when the `HttpPost` `Edit` method is called. Then you can create a `Student` entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges.` For more information, see Entity states and SaveChanges and Local Data in the MSDN Data Developer Center.

The code in *Views\Student\Edit.cshtml* is similar to what you saw in *Create.cshtml*, and no changes are required.

Run the page by selecting the **Students** tab and then clicking an **Edit** hyperlink.

Change some of the data and click **Save**. You see the changed data in the Index page.

Updating the Delete Page

In *Controllers\StudentController.cs*, the template code for the `HttpGet` `Delete` method uses the `Find` method to retrieve the selected `Student` entity, as you saw in the `Details` and `Edit` methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that is called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the `HttpPost` `Delete` method is called and then that method actually performs the delete operation.

You'll add a `try-catch` block to the `HttpPost` `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the `HttpPost` `Delete` method calls the `HttpGet` `Delete` method, passing it a parameter that indicates that an error has occurred. The `HttpGet Delete` method then redisplays the confirmation page along with the error message, giving the user an opportunity to cancel or try again.

1. Replace the `HttpGet` `Delete` action method with the following code, which manages error reporting:

```
public ActionResult Delete(bool? saveChangesError=false, int id = 0)
{
    if (saveChangesError.GetValueOrDefault())
    {
        ViewBag.ErrorMessage = "Delete failed. Try again, and if the problem persists see your system
administrator.";
    }
    Student student = db.Students.Find(id);
    if (student == null)
    {
        return HttpNotFound();
    }
    return View(student);
}
```

This code accepts an optional Boolean parameter that indicates whether it was called after a failure to save changes. This parameter is `false` when the `HttpGet` `Delete` method is called without a previous failure. When it is called by the `HttpPost` `Delete` method in response to a database update error, the parameter is `true` and an error message is passed to the view.

2. Replace the `HttpPost` `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Delete(int id)
{
    try
    {
        Student student = db.Students.Find(id);
        db.Students.Remove(student);
        db.SaveChanges();
    }
    catch (DataException/* dex */)
    {
        // uncomment dex and log error.
        return RedirectToAction("Delete", new { id = id, saveChangesError = true });
    }
    return RedirectToAction("Index");
}
```

This code retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL `DELETE` command is generated. You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code named the `HttpPost` `Delete` method `DeleteConfirmed` to give the `HttpPost` method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the `HttpPost` and `HttpGet` delete methods.

If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query to retrieve the row by replacing the lines of code that call the `Find` and `Remove` methods with the following code as shown in yellow highlight:

```
Student studentToDelete = new Student() { StudentID = id };
db.Entry(studentToDelete).State = EntityState.Deleted;
```

This code instantiates a `Student` entity using only the primary key value and then sets the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity.

As noted, the `HttpGet` `Delete` method doesn't delete the data. Performing a delete operation in response to a GET request (or for that matter, performing any edit operation, create operation, or any other operation that changes data) creates a security risk. For more information, see ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes on Stephen Walther's blog.

3. In *Views\Student\Delete.cshtml*, add an error message between the `h2` heading and the `h3` heading, as shown in the following example:

```
<h2>Delete</h2>
<p class="error">@ViewBag.ErrorMessage</p>
<h3>Are you sure you want to delete this?</h3>
```

Run the page by selecting the **Students** tab and clicking a **Delete** hyperlink:

4. Click **Delete**. The Index page is displayed without the deleted student. (You'll see an example of the error handling code in action in the Handling Concurrency tutorial later in this series.)

Ensuring that Database Connections Are Not Left Open

To make sure that database connections are properly closed and the resources they hold freed up, you should see to it that the context instance is disposed. That is why the scaffolded code provides a Dispose method at the end of the `StudentController` class in *StudentController.cs*, as shown in the following example:

```
protected override void Dispose(bool disposing)
{
    db.Dispose();
    base.Dispose(disposing);
}
```

The base `Controller` class already implements the `IDisposable` interface, so this code simply adds an override to the `Dispose(bool)` method to explicitly dispose the context instance.

Summary

You now have a complete set of pages that perform simple CRUD operations for `Student` entities. You used MVC helpers to generate UI elements for data fields. For more information about MVC helpers, see Rendering a Form Using HTML Helpers (the page is for MVC 3 but is still relevant for MVC 4).

In the next tutorial you'll expand the functionality of the Index page by adding sorting and paging.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Sorting, Filtering, and Paging with the Entity Framework in an ASP.NET MVC Application (3 of 10)

9/16/2020 • 22 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you implemented a set of web pages for basic CRUD operations for `Student` entities. In this tutorial you'll add sorting, filtering, and paging functionality to the **Students** Index page. You'll also create a page that does simple grouping.

The following illustration shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.

Add Column Sort Links to the Students Index Page

To add sorting to the Student Index page, you'll change the `Index` method of the `Student` controller and add code to the `Student` Index view.

Add Sorting Functionality to the Index Method

In *Controllers\StudentController.cs*, replace the `Index` method with the following code:

```
public ActionResult Index(string sortOrder)
{
   ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "Name_desc" : "";
   ViewBag.DateSortParm = sortOrder == "Date" ? "Date_desc" : "Date";
   var students = from s in db.Students
                  select s;
   switch (sortOrder)
   {
      case "Name_desc":
         students = students.OrderByDescending(s => s.LastName);
         break;
      case "Date":
         students = students.OrderBy(s => s.EnrollmentDate);
         break;
      case "Date_desc":
         students = students.OrderByDescending(s => s.EnrollmentDate);
         break;
      default:
         students = students.OrderBy(s => s.LastName);
         break;
   }
   return View(students.ToList());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET MVC as a parameter to the action method. The parameter will be a string that's either "Name" or "Date", optionally followed by an underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by `LastName`, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewBag` variables are used so that the view can configure the column heading hyperlinks with the appropriate query string values:

```
ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "Name_desc" : "";
ViewBag.DateSortParm = sortOrder == "Date" ? "Date_desc" : "Date";
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, `ViewBag.NameSortParm` should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

CURRENT SORT ORDER	LAST NAME HYPERLINK	DATE HYPERLINK
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an IQueryable variable before the `switch` statement, modifies it in the `switch` statement, and calls the `ToList` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query is not executed until you convert the `IQueryable` object into a collection by calling a method such as `ToList`. Therefore,

this code results in a single query that is not executed until the `return View` statement.

Add Column Heading Hyperlinks to the Student Index View

In *Views\Student\Index.cshtml*, replace the `<tr>` and `<th>` elements for the heading row with the highlighted code:

```
<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th>
            @Html.ActionLink("Last Name", "Index", new { sortOrder = ViewBag.NameSortParm })
        </th>
        <th>First Name
        </th>
        <th>
            @Html.ActionLink("Enrollment Date", "Index", new { sortOrder = ViewBag.DateSortParm })
        </th>
        <th></th>
    </tr>

    @foreach (var item in Model)
    {
```

This code uses the information in the `ViewBag` properties to set up hyperlinks with the appropriate query string values.

Run the page and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.

After you click the **Last Name** heading, students are displayed in descending last name order.

Add a Search Box to the Students Index Page

To add filtering to the Students Index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box will let you enter a string to search for in the first name and last name fields.

Add Filtering Functionality to the Index Method

In *Controllers\StudentController.cs*, replace the `Index` method with the following code (the changes are highlighted):

```
public ViewResult Index(string sortOrder, string searchString)
{
    ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
    ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in db.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
                                || s.FirstMidName.ToUpper().Contains(searchString.ToUpper()));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    return View(students.ToList());
}
```

You've added a `searchString` parameter to the `Index` method. You've also added to the LINQ statement a `where` clause that selects only students whose first name or last name contains the search string. The search string value is received from a text box that you'll add to the Index view.The statement that adds the where clause is executed only if there's a value to search for.

> **NOTE**
>
> In many cases you can call the same method either on an Entity Framework entity set or as an extension method on an in-memory collection. The results are normally the same but in some cases may be different. For example, the .NET Framework implementation of the `Contains` method returns all rows when you pass an empty string to it, but the Entity Framework provider for SQL Server Compact 4.0 returns zero rows for empty strings. Therefore the code in the example (putting the `Where` statement inside an `if` statement) makes sure that you get the same results for all versions of SQL Server. Also, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but Entity Framework SQL Server providers perform case-insensitive comparisons by default. Therefore, calling the `ToUpper` method to make the test explicitly case-insensitive ensures that results do not change when you change the code later to use a repository, which will return an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the .NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.)

Add a Search Box to the Student Index View

In *Views\Student\Index.cshtml*, add the highlighted code immediately before the opening `table` tag in order to create a caption, a text box, and a **Search** button.

```
<p>
    @Html.ActionLink("Create New", "Create")
</p>

@using (Html.BeginForm())
{
    <p>
        Find by name: @Html.TextBox("SearchString")
        <input type="submit" value="Search" /></p>
}

<table>
    <tr>
```

Run the page, enter a search string, and click **Search** to verify that filtering is working.

Notice the URL doesn't contain the "an" search string, which means that if you bookmark this page, you won't get the filtered list when you use the bookmark. You'll change the **Search** button to use query strings for filter criteria later in the tutorial.

Add Paging to the Students Index Page

To add paging to the Students Index page, you'll start by installing the **PagedList.Mvc** NuGet package. Then you'll make additional changes in the `Index` method and add paging links to the `Index` view. **PagedList.Mvc** is one of

many good paging and sorting packages for ASP.NET MVC, and its use here is intended only as an example, not as a recommendation for it over other options. The following illustration shows the paging links.

Install the PagedList.MVC NuGet Package

The NuGet **PagedList.Mvc** package automatically installs the **PagedList** package as a dependency. The **PagedList** package installs a `PagedList` collection type and extension methods for `IQueryable` and `IEnumerable` collections. The extension methods create a single page of data in a `PagedList` collection out of your `IQueryable` or `IEnumerable`, and the `PagedList` collection provides several properties and methods that facilitate paging. The **PagedList.Mvc** package installs a paging helper that displays the paging buttons.

From the **Tools** menu, select **NuGet Package Manager** and then **Manage NuGet Packages for Solution**.

In the **Manage NuGet Packages** dialog box, click the **Online** tab on the left and then enter "paged" in the search box. When you see the **PagedList.Mvc** package, click **Install**.

In the **Select Projects** box, click **OK**.

Add Paging Functionality to the Index Method

In *Controllers\StudentController.cs*, add a `using` statement for the `PagedList` namespace:

```
using PagedList;
```

Replace the `Index` method with the following code:

```
public ViewResult Index(string sortOrder, string currentFilter, string searchString, int? page)
{
   ViewBag.CurrentSort = sortOrder;
   ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
   ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";

   if (searchString != null)
   {
      page = 1;
   }
   else
   {
      searchString = currentFilter;
   }

   ViewBag.CurrentFilter = searchString;

   var students = from s in db.Students
                  select s;
   if (!String.IsNullOrEmpty(searchString))
   {
      students = students.Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
                           || s.FirstMidName.ToUpper().Contains(searchString.ToUpper()));
   }
   switch (sortOrder)
   {
      case "name_desc":
         students = students.OrderByDescending(s => s.LastName);
         break;
      case "Date":
         students = students.OrderBy(s => s.EnrollmentDate);
         break;
      case "date_desc":
         students = students.OrderByDescending(s => s.EnrollmentDate);
         break;
      default:  // Name ascending
         students = students.OrderBy(s => s.LastName);
         break;
   }

   int pageSize = 3;
   int pageNumber = (page ?? 1);
   return View(students.ToPagedList(pageNumber, pageSize));
}
```

This code adds a `page` parameter, a current sort order parameter, and a current filter parameter to the method signature, as shown here:

```
public ActionResult Index(string sortOrder, string currentFilter, string searchString, int? page)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters will be null. If a paging link is clicked, the `page` variable will contain the page number to display.

`A ViewBag` property provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging:

```
ViewBag.CurrentSort = sortOrder;
```

Another property, `ViewBag.CurrentFilter`, provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed. If the search string is changed during paging, the page has to be reset to 1,

because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the submit button is pressed. In that case, the `searchString` parameter is not null.

```
if (searchString != null)
        page = 1;
else
    searchString = currentFilter;
```

At the end of the method, the `ToPagedList` extension method on the students `IQueryable` object converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view:

```
int pageSize = 3;
int pageNumber = (page ?? 1);
return View(students.ToPagedList(pageNumber, pageSize));
```

The `ToPagedList` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(page ?? 1)` means return the value of `page` if it has a value, or return 1 if `page` is null.

Add Paging Links to the Student Index View

In *Views\Student\Index.cshtml*, replace the existing code with the following code:

```
@model PagedList.IPagedList<ContosoUniversity.Models.Student>
@using PagedList.Mvc;
<link href="~/Content/PagedList.css" rel="stylesheet" type="text/css" />

@{
    ViewBag.Title = "Students";
}

<h2>Students</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
@using (Html.BeginForm("Index", "Student", FormMethod.Get))
{
    <p>
        Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
        <input type="submit" value="Search" />
    </p>
}
<table>
<tr>
    <th></th>
    <th>
        @Html.ActionLink("Last Name", "Index", new { sortOrder=ViewBag.NameSortParm,
currentFilter=ViewBag.CurrentFilter })
    </th>
    <th>
        First Name
    </th>
    <th>
        @Html.ActionLink("Enrollment Date", "Index", new { sortOrder = ViewBag.DateSortParm, currentFilter =
ViewBag.CurrentFilter })
    </th>
</tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.StudentID }) |
            @Html.ActionLink("Details", "Details", new { id=item.StudentID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.StudentID })
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.LastName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.FirstMidName)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
    </tr>
}

</table>
<br />
Page @(Model.PageCount < Model.PageNumber ? 0 : Model.PageNumber) of @Model.PageCount

@Html.PagedListPager( Model, page => Url.Action("Index", new { page, sortOrder = ViewBag.CurrentSort,
currentFilter=ViewBag.CurrentFilter }) )
```

The `@model` statement at the top of the page specifies that the view now gets a `PagedList` object instead of a `List` object.

The `using` statement for `PagedList.Mvc` gives access to the MVC helper for the paging buttons.

The code uses an overload of BeginForm that allows it to specify FormMethod.Get.

```
@using (Html.BeginForm("Index", "Student", FormMethod.Get))
{
    <p>
        Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
        <input type="submit" value="Search" />
    </p>
}
```

The default BeginForm submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines for the use of HTTP GET specify that you should use GET when the action does not result in an update.

The text box is initialized with the current search string so when you click a new page you can see the current search string.

```
Find by name: @Html.TextBox("SearchString", ViewBag.CurrentFilter as string)
```

The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

```
@Html.ActionLink("Last Name", "Index", new { sortOrder=ViewBag.NameSortParm,
currentFilter=ViewBag.CurrentFilter })
```

The current page and total number of pages are displayed.

```
Page @(Model.PageCount < Model.PageNumber ? 0 : Model.PageNumber) of @Model.PageCount
```

If there are no pages to display, "Page 0 of 0" is shown. (In that case the page number is greater than the page count because `Model.PageNumber` is 1, and `Model.PageCount` is 0.)

The paging buttons are displayed by the `PagedListPager` helper:

```
@Html.PagedListPager( Model, page => Url.Action("Index", new { page }) )
```

The `PagedListPager` helper provides a number of options that you can customize, including URLs and styling. For more information, see TroyGoode / PagedList on the GitHub site.

Run the page.

Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About Page That Shows Student Statistics

For the Contoso University website's About page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Modify the `About` method in the `Home` controller.
- Modify the `About` view.

Create the View Model

Create a *ViewModels* folder. In that folder, add a class file *EnrollmentDateGroup.cs* and replace the existing code with the following code:

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.ViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

In *HomeController.cs*, add the following `using` statements at the top of the file:

```
using ContosoUniversity.DAL;
using ContosoUniversity.ViewModels;
```

Add a class variable for the database context immediately after the opening curly brace for the class:

```
public class HomeController : Controller
{
    private SchoolContext db = new SchoolContext();
```

Replace the `About` method with the following code:

```
public ActionResult About()
{
    var data = from student in db.Students
               group student by student.EnrollmentDate into dateGroup
               select new EnrollmentDateGroup()
               {
                   EnrollmentDate = dateGroup.Key,
                   StudentCount = dateGroup.Count()
               };
    return View(data);
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Add a `Dispose` method:

```
protected override void Dispose(bool disposing)
{
    db.Dispose();
    base.Dispose(disposing);
}
```

Modify the About View

Replace the code in the *Views\Home\About.cshtml* file with the following code:

```
@model IEnumerable<ContosoUniversity.ViewModels.EnrollmentDateGroup>

@{
    ViewBag.Title = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.EnrollmentDate)
        </td>
        <td>
            @item.StudentCount
        </td>
    </tr>
}
</table>
```

Run the app and click the **About** link. The count of students for each enrollment date is displayed in a table.

Optional: Deploy the app to Windows Azure

So far your application has been running locally in IIS Express on your development computer. To make it available

for other people to use over the Internet, you have to deploy it to a web hosting provider. In this optional section of the tutorial you'll deploy it to a Windows Azure Web Site.

Using Code First Migrations to Deploy the Database

To deploy the database you'll use Code First Migrations. When you create the publish profile that you use to configure settings for deploying from Visual Studio, you'll select a check box that is labeled **Execute Code First Migrations (runs on application start)**. This setting causes the deployment process to automatically configure the application *Web.config* file on the destination server so that Code First uses the `MigrateDatabaseToLatestVersion` initializer class.

Visual Studio does not do anything with the database during the deployment process. When the deployed application accesses the database for the first time after deployment, Code First automatically creates the database or updates the database schema to the latest version. If the application implements a Migrations `Seed` method, the method runs after the database is created or the schema is updated.

Your Migrations `Seed` method inserts test data. If you were deploying to a production environment, you would have to change the `Seed` method so that it only inserts data that you want to be inserted into your production database. For example, in your current data model you might want to have real courses but fictional students in the development database. You can write a `Seed` method to load both in development, and then comment out the fictional students before you deploy to production. Or you can write a `Seed` method to load only courses, and enter the fictional students in the test database manually by using the application's UI.

Get a Windows Azure account

You'll need a Windows Azure account. If you don't already have one, you can create a free trial account in just a couple of minutes. For details, see Windows Azure Free Trial.

Create a web site and a SQL database in Windows Azure

Your Windows Azure Web Site will run in a shared hosting environment, which means it runs on virtual machines (VMs) that are shared with other Windows Azure clients. A shared hosting environment is a low-cost way to get started in the cloud. Later, if your web traffic increases, the application can scale to meet the need by running on dedicated VMs. If you need a more complex architecture, you can migrate to a Windows Azure Cloud Service. Cloud services run on dedicated VMs that you can configure according to your needs.

Windows Azure SQL Database is a cloud-based relational database service that is built on SQL Server technologies. Tools and applications that work with SQL Server also work with SQL Database.

1. In the Windows Azure Management Portal, click **Web Sites** in the left tab, and then click **New**.

2. Click **CUSTOM CREATE**.

The **New Web Site - Custom Create** wizard opens.

3. In the **New Web Site** step of the wizard, enter a string in the **URL** box to use as the unique URL for your application. The complete URL will consist of what you enter here plus the suffix that you see next to the text box. The illustration shows "ConU", but that URL is probably taken so you will have to choose a different one.

4. In the **Region** drop-down list, choose a region close to you. This setting specifies which data center your web site will run in.

5. In the **Database** drop-down list, choose **Create a free 20 MB SQL database**.

6. In the **DB CONNECTION STRING NAME**, enter *SchoolContext*.

7. Click the arrow that points to the right at the bottom of the box. The wizard advances to the **Database Settings** step.

8. In the **Name** box, enter *ContosoUniversityDB*.

9. In the **Server** box, select **New SQL Database server**. Alternatively, if you previously created a server, you can select that server from the drop-down list.

10. Enter an administrator **LOGIN NAME** and **PASSWORD**. If you selected **New SQL Database server** you aren't entering an existing name and password here, you're entering a new name and password that you're defining now to use later when you access the database. If you selected a server that you created previously, you'll enter credentials for that server. For this tutorial, you won't select the ***Advanced*** check box. The ***Advanced*** options enable you to set the database collation.

11. Choose the same **Region** that you chose for the web site.

12. Click the check mark at the bottom right of the box to indicate that you're finished.

The following image shows using an existing SQL Server and Login.

The Management Portal returns to the Web Sites page, and the **Status** column shows that the site is being created. After a while (typically less than a minute), the **Status** column shows that the site was successfully created. In the navigation bar at the left, the number of sites you have in your account appears next to the **Web Sites** icon, and the number of databases appears next to the **SQL Databases** icon.

Deploy the application to Windows Azure

1. In Visual Studio, right-click the project in **Solution Explorer** and select **Publish** from the context menu.

2. In the **Profile** tab of the **Publish Web** wizard, click **Import**.

3. If you have not previously added your Windows Azure subscription in Visual Studio, perform the following steps. In these steps you add your subscription so that the drop-down list under **Import from a Windows Azure web site** will include your web site.

   a. In the **Import Publish Profile** dialog box, click **Import from a Windows Azure web site**, and then click **Add Windows Azure subscription**.

   b. In the **Import Windows Azure Subscriptions** dialog box, click **Download subscription file**.

   c. In your browser window, save the *.publishsettings* file.

WARNING

Security - The *publishsettings* file contains your credentials (unencoded) that are used to administer your Windows Azure subscriptions and services. The security best practice for this file is to store it temporarily outside your source directories (for example in the *Libraries\Documents* folder), and then delete it once the import has completed. A malicious user who gains access to the `.publishsettings` file can edit, create, and delete your Windows Azure services.

d. In the **Import Windows Azure Subscriptions** dialog box, click **Browse** and navigate to the *.publishsettings* file.

e. Click **Import**.

4. In the **Import Publish Profile** dialog box, select **Import from a Windows Azure web site**, select your web site from the drop-down list, and then click **OK**.

5. In the **Connection** tab, click **Validate Connection** to make sure that the settings are correct.

6. When the connection has been validated, a green check mark is shown next to the **Validate Connection** button. Click **Next**.

7. Open the **Remote connection string** drop-down list under **SchoolContext** and select the connection string for the database you created.

8. Select **Execute Code First Migrations (runs on application start)**.

9. Uncheck **Use this connection string at runtime** for the **UserContext (DefaultConnection)**, since this application is not using the membership database.

10. Click **Next**.

11. In the **Preview** tab, click **Start Preview**.

The tab displays a list of the files that will be copied to the server. Displaying the preview isn't required to publish the application but is a useful function to be aware of. In this case, you don't need to do anything with the list of files that is displayed. The next time you deploy this application, only the files that have changed will be in this list.

12. Click **Publish**.
    Visual Studio begins the process of copying the files to the Windows Azure server.

13. The **Output** window shows what deployment actions were taken and reports successful completion of the deployment.

```
Output
Show output from: Build
2>Adding file (example1\Views\Home\Contact.cshtml).
2>Adding file (example1\Views\Home\Index.cshtml).
2>Adding file (example1\Views\Shared\Error.cshtml).
2>Adding file (example1\Views\Shared\_Layout.cshtml).
2>Adding file (example1\Views\Shared\_LoginPartial.cshtml).
2>Adding file (example1\Views\Web.config).
2>Adding file (example1\Views\_ViewStart.cshtml).
2>Adding file (example1\Web.config).
2>Adding ACL's for path (example1)
2>Adding ACL's for path (example1)
2>Publish is successfully deployed.
2>Site was published successfully http://example1.azurewebsites.net/
========== Build: 1 succeeded, 0 failed, 0 up-to-date, 0 skipped ==========
========== Publish: 1 succeeded, 0 failed, 0 skipped ==========
```

14. Upon successful deployment, the default browser automatically opens to the URL of the deployed web site. The application you created is now running in the cloud. Click the Students tab.

At this point your *SchoolContext* database has been created in the Windows Azure SQL Database because you selected **Execute Code First Migrations (runs on app start)**. The *Web.config* file in the deployed web site has been changed so that the MigrateDatabaseToLatestVersion initializer would run the first time your code reads or writes data in the database (which happened when you selected the **Students** tab):

```
</runtime>
  <entityFramework>
    <defaultConnectionFactory type="System.Data.Entity.Infrastructure.LocalDbConnectionFa
      <parameters>
        <parameter value="v11.0" />
      </parameters>
    </defaultConnectionFactory>
    <contexts>
      <context type="ContosoUniversity.Models.SchoolContext, ContosoUniversity">
        <databaseInitializer type="System.Data.Entity.MigrateDatabaseToLatestVersion`2[
                              [ContosoUniversity.Models.SchoolContext, ContosoUniversity],
                              [ContosoUniversity.Migrations.Configuration, ContosoUniversi
                              EntityFramework, PublicKeyToken=b77a5c561934e089">
          <parameters>
            <parameter value="SchoolContext_DatabasePublish"/>
          </parameters>
        </databaseInitializer>
      </context>
    </contexts>
  </entityFramework>
</configuration>
```

The deployment process also created a new connection string *(SchoolContext_DatabasePublish)* for Code First Migrations to use for updating the database schema and seeding the database.

```
<connectionStrings>
    <add name="DefaultConnection" connectionString="Data Source=(LocalDb)\v11.0;Initial
    <add name="SchoolContext" connectionString="Data Source=tcp:d015leqjqx.database.winc
    <add name="SchoolContext_DatabasePublish" connectionString="Data Source=tcp:d015leq
</connectionStrings>
```

The *DefaultConnection* connection string is for the membership database (which we are not using in this tutorial). The *SchoolContext* connection string is for the ContosoUniversity database.

You can find the deployed version of the Web.config file on your own computer in *ContosoUniversity\obj\Release\Package\PackageTmp\Web.config*. You can access the deployed *Web.config* file itself by using FTP. For instructions, see ASP.NET Web Deployment using Visual Studio: Deploying a Code Update. Follow the instructions that start with "To use an FTP tool, you need three things: the FTP URL, the user name, and the password."

> **NOTE**
>
> The web app doesn't implement security, so anyone who finds the URL can change the data. For instructions on how to secure the web site, see Deploy a Secure ASP.NET MVC app with Membership, OAuth, and SQL Database to a Windows Azure Web Site. You can prevent other people from using the site by using the Windows Azure Management Portal or **Server Explorer** in Visual Studio to stop the site.

Code First Initializers

In the deployment section you saw the MigrateDatabaseToLatestVersion initializer being used. Code First also provides other initializers that you can use, including CreateDatabaseIfNotExists (the default), DropCreateDatabaseIfModelChanges and DropCreateDatabaseAlways. The `DropCreateAlways` initializer can be useful for setting up conditions for unit tests. You can also write your own initializers, and you can call an initializer explicitly if you don't want to wait until the application reads from or writes to the database. For a comprehensive explanation of initializers, see chapter 6 of the book Programming Entity Framework: Code First by Julie Lerman and Rowan Miller.

Summary

In this tutorial you've seen how to create a data model and implement basic CRUD, sorting, filtering, paging, and grouping functionality. In the next tutorial you'll begin looking at more advanced topics by expanding the data model.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Creating a More Complex Data Model for an ASP.NET MVC Application (4 of 10)

2/20/2020 • 31 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorials you worked with a simple data model that was composed of three entities. In this tutorial you'll add more entities and relationships and you'll customize the data model by specifying formatting, validation, and database mapping rules. You'll see two ways to customize the data model: by adding attributes to entity classes and by adding code to the database context class.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:

Customize the Data Model by Using Attributes

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete `School` data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType Attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In *Models\Student.cs*, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int StudentID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The DataType attribute is used to specify a data type that is more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The DataType Enumeration provides for many data types, such as *Date, Time, PhoneNumber, Currency, EmailAddress* and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for DataType.EmailAddress, and a date selector can be provided for DataType.Date in browsers that support HTML5. The DataType attributes emits HTML 5 data- (pronounced *data dash*) attributes that HTML 5 browsers can understand. The DataType attributes do not provide any validation.

`DataType.Date` does not specify the format of the date that is displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
public DateTime EnrollmentDate { get; set; }
```

The `ApplyFormatInEditMode` setting specifies that the specified formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields — for example, for currency values, you might not want the currency symbol in the text box for editing.)

You can use the DisplayFormat attribute by itself, but it's generally a good idea to use the DataType attribute also. The `DataType` attribute conveys the *semantics* of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, etc.).
- By default, the browser will render data using the correct format based on your locale.
- The DataType attribute can enable MVC to choose the right field template to render the data (the DisplayFormat if used by itself uses the string template). For more information, see Brad Wilson's ASP.NET MVC 2 Templates. (Though written for MVC 2, this article still applies to the current version of ASP.NET MVC.)

If you use the `DataType` attribute with a date field, you have to specify the `DisplayFormat` attribute also in order to ensure that the field renders correctly in Chrome browsers. For more information, see this StackOverflow thread.

Run the Student Index page again and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the `Student` model.

The StringLengthAttribute

You can also specify data validation rules and messages using attributes. Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add StringLength attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int StudentID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The StringLength attribute won't prevent a user from entering white space for a name. You can use the RegularExpression attribute to apply restrictions to the input. For example the following code requires the first character to be upper case and the remaining characters to be alphabetical:

```
[RegularExpression(@"^[A-Z]+[a-zA-Z""'\s-]*$")]
```

The MaxLength attribute provides similar functionality to the StringLength attribute but doesn't provide client side validation.

Run the application and click the **Students** tab. You get the following error:

The model backing the 'SchoolContext' context has changed since the database was created. Consider using Code First Migrations to update the database (https://go.microsoft.com/fwlink/?LinkId=238269).

The database model has changed in a way that requires a change in the database schema, and Entity Framework detected that. You'll use migrations to update the schema without losing any data that you added to the database by using the UI. If you changed data that was created by the `Seed` method, that will be changed back to its original state because of the AddOrUpdate method that you're using in the `Seed` method. (AddOrUpdate is equivalent to an "upsert" operation from database terminology.)

In the Package Manager Console (PMC), enter the following commands:

```
add-migration MaxLengthOnNames
update-database
```

The `add-migration MaxLengthOnNames` command creates a file named *<timeStamp>_MaxLengthOnNames.cs*. This file contains code that will update the database to match the current data model. The timestamp prepended to the migrations file name is used by Entity Framework to order the migrations. After you have created multiple migrations, if you drop the database, or if you deploy the project by using Migrations, all of the migrations are applied in the order in which they were created.

Run the **Create** page, and enter either name longer than 50 characters. As soon as you exceed 50 characters, client side validation immediately shows an error message.

The Column Attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you had used the name `FirstMidName` for the first-name field because the field might also contain a middle name. But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they are given the same name as the property name.

Add a using statement for System.ComponentModel.DataAnnotations.Schema and the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int StudentID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50, ErrorMessage = "First name cannot be longer than 50 characters.")]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The addition of the Column attribute changes the model backing the SchoolContext, so it won't match the database. Enter the following commands in the PMC to create another migration:

```
add-migration ColumnFirstName
update-database
```

In **Server Explorer** (**Database Explorer** if you are using Express for Web), double-click the *Student* table.

The following image shows the original column name as it was before you applied the first two migrations. In addition to the column name changing from `FirstMidName` to `FirstName`, the two name columns have changed from `MAX` length to 50 characters.

You can also make database mapping changes using the Fluent API, as you'll see later in this tutorial.

> **NOTE**
> If you try to compile before you finish creating all of these entity classes, you might get compiler errors.

Create the Instructor Entity

Create *Models\Instructor.cs*, replacing the template code with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int InstructorID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public virtual ICollection<Course> Courses { get; set; }
        public virtual OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the `Student` and `Instructor` entities. In the Implementing Inheritance tutorial later in this series, you'll refactor using inheritance to eliminate this redundancy.

The Required and Display Attributes

The attributes on the `LastName` property specify that it's a required field, that the caption for the text box should

be "Last Name" (instead of the property name, which would be "LastName" with no space), and that the value can't be longer than 50 characters.

```
[Required]
[Display(Name="Last Name")]
[StringLength(50)]
public string LastName { get; set; }
```

The StringLength attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema. The Required attribute is not needed for value types such as DateTime, int, double, and float. Value types cannot be assigned a null value, so they are inherently required. You could remove the Required attribute and replace it with a minimum length parameter for the `StringLength` attribute:

```
[Display(Name = "Last Name")]
[StringLength(50, MinimumLength=1)]
public string LastName { get; set; }
```

You can put multiple attributes on one line, so you could also write the instructor class as follows:

```
public class Instructor
{
   public int InstructorID { get; set; }

   [Display(Name = "Last Name"),StringLength(50, MinimumLength=1)]
   public string LastName { get; set; }

   [Column("FirstName"),Display(Name = "First Name"),StringLength(50, MinimumLength=1)]
   public string FirstMidName { get; set; }

   [DataType(DataType.Date),Display(Name = "Hire Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
   public DateTime HireDate { get; set; }

   public string FullName
   {
      get { return LastName + ", " + FirstMidName; }
   }

   public virtual ICollection<Course> Courses { get; set; }
   public virtual OfficeAssignment OfficeAssignment { get; set; }
}
```

The FullName Calculated Property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a `get` accessor, and no `FullName` column will be generated in the database.

```
public string FullName
{
    get { return LastName + ", " + FirstMidName; }
}
```

The Courses and OfficeAssignment Navigation Properties

The `Courses` and `OfficeAssignment` properties are navigation properties. As was explained earlier, they are typically defined as virtual so that they can take advantage of an Entity Framework feature called lazy loading. In addition, if a navigation property can hold multiple entities, its type must implement the ICollection<T> Interface.

(For example IList<T> qualifies but not IEnumerable<T> because `IEnumerable<T>` doesn't implement Add.

An instructor can teach any number of courses, so `Courses` is defined as a collection of `Course` entities. Our business rules state an instructor can only have at most one office, so `OfficeAssignment` is defined as a single `OfficeAssignment` entity (which may be `null` if no office is assigned).

```
public virtual ICollection<Course> Courses { get; set; }
public virtual OfficeAssignment OfficeAssignment { get; set; }
```

Create the OfficeAssignment Entity

Create *Models\OfficeAssignment.cs* with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        [ForeignKey("Instructor")]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public virtual Instructor Instructor { get; set; }
    }
}
```

Build the project, which saves your changes and verifies you haven't made any copy and paste errors the compiler can catch.

The Key Attribute

There's a one-to-zero-or-one relationship between the `Instructor` and the `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the `Instructor` entity. But the Entity Framework can't automatically recognize `InstructorID` as the primary key of this entity because its name doesn't follow the `ID` or *classname* `ID` naming convention. Therefore, the `Key` attribute is used to identify it as the key:

```
[Key]
[ForeignKey("Instructor")]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something different than `classnameID` or `ID`. By default EF treats the key as non-database-generated because the column is for an identifying relationship.

The ForeignKey Attribute

When there is a one-to-zero-or-one relationship or a one-to-one relationship between two entities (such as between `OfficeAssignment` and `Instructor`), EF can't work out which end of the relationship is the principal and which end is dependent. One-to-one relationships have a reference navigation property in each class to the other class. The ForeignKey Attribute can be applied to the dependent class to establish the relationship. If you omit the ForeignKey Attribute, you get the following error when you try to create the migration:

Unable to determine the principal end of an association between the types 'ContosoUniversity.Models.OfficeAssignment' and 'ContosoUniversity.Models.Instructor'. The principal end of this association must be explicitly configured using either the relationship fluent API or data annotations.

Later in the tutorial we'll show how to configure this relationship with the fluent API.

The Instructor Navigation Property

The `Instructor` entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the `OfficeAssignment` entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an `Instructor` entity has a related `OfficeAssignment` entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the InstructorID foreign key (which is also the key to this table) is non-nullable.

Modify the Course Entity

In *Models\Course.cs*, replace the code you added earlier with the following code:

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public class Course
   {
      [DatabaseGenerated(DatabaseGeneratedOption.None)]
      [Display(Name = "Number")]
      public int CourseID { get; set; }

      [StringLength(50, MinimumLength = 3)]
      public string Title { get; set; }

      [Range(0, 5)]
      public int Credits { get; set; }

      [Display(Name = "Department")]
      public int DepartmentID { get; set; }

      public virtual Department Department { get; set; }
      public virtual ICollection<Enrollment> Enrollments { get; set; }
      public virtual ICollection<Instructor> Instructors { get; set; }
   }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related `Department` entity and it has a `Department` navigation property. The Entity Framework doesn't require you to add a foreign key property to your data model when you have a navigation property for a related entity. EF automatically creates foreign keys in the database wherever they are needed. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a course entity to edit, the `Department` entity is null if you don't load it, so when you update the course entity, you would have to first fetch the `Department` entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the `Department` entity before you update.

The DatabaseGenerated Attribute

The DatabaseGenerated attribute with the None parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, the Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for `Course` entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

Foreign Key and Navigation Properties

The foreign key properties and navigation properties in the `Course` entity reflect the following relationships:

- A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

  ```
  public int DepartmentID { get; set; }
  public virtual Department Department { get; set; }
  ```

- A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

```
public virtual ICollection<Enrollment> Enrollments { get; set; }
```

- A course may be taught by multiple instructors, so the `Instructors` navigation property is a collection:

```
public virtual ICollection<Instructor> Instructors { get; set; }
```

Creating the Department Entity

Create *Models\Department.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public class Department
   {
      public int DepartmentID { get; set; }

      [StringLength(50, MinimumLength=3)]
      public string Name { get; set; }

      [DataType(DataType.Currency)]
      [Column(TypeName = "money")]
      public decimal Budget { get; set; }

      [DataType(DataType.Date)]
      public DateTime StartDate { get; set; }

      [Display(Name = "Administrator")]
      public int? InstructorID { get; set; }

      public virtual Instructor Administrator { get; set; }
      public virtual ICollection<Course> Courses { get; set; }
   }
}
```

The Column Attribute

Earlier you used the Column attribute to change column name mapping. In the code for the `Department` entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server money type in the database:

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework usually chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that.

Foreign Key and Navigation Properties

The foreign key and navigation properties reflect the following relationships:

- A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the `Instructor` entity, and a question mark is added after the `int` type designation to mark the property as nullable.The navigation property is named `Administrator` but holds an `Instructor` entity:

  ```
  public int? InstructorID { get; set; }
  public virtual Instructor Administrator { get; set; }
  ```

- A department may have many courses, so there's a `Courses` navigation property:

  ```
  public virtual ICollection<Course> Courses { get; set; }
  ```

  > **NOTE**
  > By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when your initializer code runs. For example, if you didn't define the `Department.InstructorID` property as nullable, you'd get the following exception message when the initializer runs: "The referential relationship will result in a cyclical reference that's not allowed." If your business rules required `InstructorID` property as non-nullable, you would have to use the following fluent API to disable cascade delete on the relationship:

```
modelBuilder.Entity().HasRequired(d => d.Administrator).WithMany().WillCascadeOnDelete(false);
```

Modifying the Student Entity

In *Models\Student.cs*, replace the code you added earlier with the following code. The changes are highlighted.

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public class Student
   {
      public int StudentID { get; set; }

      [StringLength(50, MinimumLength = 1)]
      public string LastName { get; set; }

      [StringLength(50, MinimumLength = 1, ErrorMessage = "First name cannot be longer than 50 characters.")]
      [Column("FirstName")]
      public string FirstMidName { get; set; }

      [DataType(DataType.Date)]
      [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode = true)]
      [Display(Name = "Enrollment Date")]
      public DateTime EnrollmentDate { get; set; }

      public string FullName
      {
         get { return LastName + ", " + FirstMidName; }
      }

      public virtual ICollection<Enrollment> Enrollments { get; set; }
   }
}
```

The Enrollment Entity

In *Models\Enrollment.cs*, replace the code you added earlier with the following code

```
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }

        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public virtual Course Course { get; set; }
        public virtual Student Student { get; set; }
    }
}
```

Foreign Key and Navigation Properties

The foreign key properties and navigation properties reflect the following relationships:

- An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course`

navigation property:

```
public int CourseID { get; set; }
public virtual Course Course { get; set; }
```

- An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:

```
public int StudentID { get; set; }
public virtual Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities, and the `Enrollment` entity functions as a many-to-many join table *with payload* in the database. This means that the `Enrollment` table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a `Grade` property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)

Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two foreign keys `CourseID` and `StudentID`. In that case, it would correspond to a many-to-many join table *without payload* (or a *pure join table*) in the database, and you wouldn't have to create a model class for it at all. The `Instructor` and `Course` entities have that kind of many-to-many relationship, and as you can see, there is no entity class between them:

A join table is required in the database, however, as shown in the following database diagram:

The Entity Framework automatically creates the `CourseInstructor` table, and you read and update it indirectly by reading and updating the `Instructor.Courses` and `Course.Instructors` navigation properties.

Entity Diagram Showing Relationships

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.

Besides the many-to-many relationship lines (* to *) and the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment` entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Customize the Data Model by adding Code to the Database Context

Next you'll add the new entities to the `SchoolContext` class and customize some of the mapping using fluent API calls. (The API is "fluent" because it's often used by stringing a series of method calls together into a single statement.)

In this tutorial you'll use the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible.

To add the new entities to the data model and perform database mapping that you didn't do by using attributes, replace the code in *DAL\SchoolContext.cs* with the following code:

```
using ContosoUniversity.Models;
using System.Data.Entity;
using System.Data.Entity.ModelConfiguration.Conventions;

namespace ContosoUniversity.DAL
{
   public class SchoolContext : DbContext
   {
      public DbSet<Course> Courses { get; set; }
      public DbSet<Department> Departments { get; set; }
      public DbSet<Enrollment> Enrollments { get; set; }
      public DbSet<Instructor> Instructors { get; set; }
      public DbSet<Student> Students { get; set; }
      public DbSet<OfficeAssignment> OfficeAssignments { get; set; }

      protected override void OnModelCreating(DbModelBuilder modelBuilder)
      {
         modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();

         modelBuilder.Entity<Course>()
             .HasMany(c => c.Instructors).WithMany(i => i.Courses)
             .Map(t => t.MapLeftKey("CourseID")
                 .MapRightKey("InstructorID")
                 .ToTable("CourseInstructor"));
      }
   }
}
```

The new statement in the OnModelCreating method configures the many-to-many join table:

- For the many-to-many relationship between the `Instructor` and `Course` entities, the code specifies the table and column names for the join table. Code First can configure the many-to-many relationship for you without this code, but if you don't call it, you will get default names such as `InstructorInstructorID` for the `InstructorID` column.

  ```
  modelBuilder.Entity<Course>()
      .HasMany(c => c.Instructors).WithMany(i => i.Courses)
      .Map(t => t.MapLeftKey("CourseID")
          .MapRightKey("InstructorID")
          .ToTable("CourseInstructor"));
  ```

The following code provides an example of how you could have used fluent API instead of attributes to specify the relationship between the `Instructor` and `OfficeAssignment` entities:

```
modelBuilder.Entity<Instructor>()
    .HasOptional(p => p.OfficeAssignment).WithRequired(p => p.Instructor);
```

For information about what "fluent API" statements are doing behind the scenes, see the Fluent API blog post.

Seed the Database with Test Data

Replace the code in the *Migrations\Configuration.cs* file with the following code in order to provide seed data for the new entities you've created.

```
namespace ContosoUniversity.Migrations
{
   using System;
   using System.Collections.Generic;
   using System.Data.Entity;
```

```
using System.Data.Entity.Migrations;
using System.Linq;
using ContosoUniversity.Models;
using ContosoUniversity.DAL;

internal sealed class Configuration : DbMigrationsConfiguration<SchoolContext>
{
   public Configuration()
   {
      AutomaticMigrationsEnabled = false;
   }

   protected override void Seed(SchoolContext context)
   {
      var students = new List<Student>
         {
             new Student { FirstMidName = "Carson",   LastName = "Alexander",
                 EnrollmentDate = DateTime.Parse("2010-09-01") },
             new Student { FirstMidName = "Meredith", LastName = "Alonso",
                 EnrollmentDate = DateTime.Parse("2012-09-01") },
             new Student { FirstMidName = "Arturo",   LastName = "Anand",
                 EnrollmentDate = DateTime.Parse("2013-09-01") },
             new Student { FirstMidName = "Gytis",    LastName = "Barzdukas",
                 EnrollmentDate = DateTime.Parse("2012-09-01") },
             new Student { FirstMidName = "Yan",      LastName = "Li",
                 EnrollmentDate = DateTime.Parse("2012-09-01") },
             new Student { FirstMidName = "Peggy",    LastName = "Justice",
                 EnrollmentDate = DateTime.Parse("2011-09-01") },
             new Student { FirstMidName = "Laura",    LastName = "Norman",
                 EnrollmentDate = DateTime.Parse("2013-09-01") },
             new Student { FirstMidName = "Nino",     LastName = "Olivetto",
                 EnrollmentDate = DateTime.Parse("2005-09-01") }
         };

      students.ForEach(s => context.Students.AddOrUpdate(p => p.LastName, s));
      context.SaveChanges();

      var instructors = new List<Instructor>
         {
             new Instructor { FirstMidName = "Kim",     LastName = "Abercrombie",
                 HireDate = DateTime.Parse("1995-03-11") },
             new Instructor { FirstMidName = "Fadi",    LastName = "Fakhouri",
                 HireDate = DateTime.Parse("2002-07-06") },
             new Instructor { FirstMidName = "Roger",   LastName = "Harui",
                 HireDate = DateTime.Parse("1998-07-01") },
             new Instructor { FirstMidName = "Candace", LastName = "Kapoor",
                 HireDate = DateTime.Parse("2001-01-15") },
             new Instructor { FirstMidName = "Roger",   LastName = "Zheng",
                 HireDate = DateTime.Parse("2004-02-12") }
         };
      instructors.ForEach(s => context.Instructors.AddOrUpdate(p => p.LastName, s));
      context.SaveChanges();

      var departments = new List<Department>
         {
             new Department { Name = "English",     Budget = 350000,
                 StartDate = DateTime.Parse("2007-09-01"),
                 InstructorID  = instructors.Single( i => i.LastName == "Abercrombie").InstructorID },
             new Department { Name = "Mathematics", Budget = 100000,
                 StartDate = DateTime.Parse("2007-09-01"),
                 InstructorID  = instructors.Single( i => i.LastName == "Fakhouri").InstructorID },
             new Department { Name = "Engineering", Budget = 350000,
                 StartDate = DateTime.Parse("2007-09-01"),
                 InstructorID  = instructors.Single( i => i.LastName == "Harui").InstructorID },
             new Department { Name = "Economics",   Budget = 100000,
                 StartDate = DateTime.Parse("2007-09-01"),
                 InstructorID  = instructors.Single( i => i.LastName == "Kapoor").InstructorID }
         };
      departments.ForEach(s => context.Departments.AddOrUpdate(p => p.Name, s));
```

```
            context.SaveChanges();

            var courses = new List<Course>
               {
                   new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
                     DepartmentID = departments.Single( s => s.Name == "Engineering").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 4022, Title = "Microeconomics", Credits = 3,
                     DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 4041, Title = "Macroeconomics", Credits = 3,
                     DepartmentID = departments.Single( s => s.Name == "Economics").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 1045, Title = "Calculus",       Credits = 4,
                     DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 3141, Title = "Trigonometry",   Credits = 4,
                     DepartmentID = departments.Single( s => s.Name == "Mathematics").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 2021, Title = "Composition",    Credits = 3,
                     DepartmentID = departments.Single( s => s.Name == "English").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
                   new Course {CourseID = 2042, Title = "Literature",     Credits = 4,
                     DepartmentID = departments.Single( s => s.Name == "English").DepartmentID,
                     Instructors = new List<Instructor>()
                   },
               };
            courses.ForEach(s => context.Courses.AddOrUpdate(p => p.CourseID, s));
            context.SaveChanges();

            var officeAssignments = new List<OfficeAssignment>
               {
                   new OfficeAssignment {
                       InstructorID = instructors.Single( i => i.LastName == "Fakhouri").InstructorID,
                       Location = "Smith 17" },
                   new OfficeAssignment {
                       InstructorID = instructors.Single( i => i.LastName == "Harui").InstructorID,
                       Location = "Gowan 27" },
                   new OfficeAssignment {
                       InstructorID = instructors.Single( i => i.LastName == "Kapoor").InstructorID,
                       Location = "Thompson 304" },
               };
            officeAssignments.ForEach(s => context.OfficeAssignments.AddOrUpdate(p => p.Location, s));
            context.SaveChanges();

            AddOrUpdateInstructor(context, "Chemistry", "Kapoor");
            AddOrUpdateInstructor(context, "Chemistry", "Harui");
            AddOrUpdateInstructor(context, "Microeconomics", "Zheng");
            AddOrUpdateInstructor(context, "Macroeconomics", "Zheng");

            AddOrUpdateInstructor(context, "Calculus", "Fakhouri");
            AddOrUpdateInstructor(context, "Trigonometry", "Harui");
            AddOrUpdateInstructor(context, "Composition", "Abercrombie");
            AddOrUpdateInstructor(context, "Literature", "Abercrombie");

            context.SaveChanges();

            var enrollments = new List<Enrollment>
               {
                   new Enrollment {
                       StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                       CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID,
                       Grade = Grade.A
```

```
            },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                CourseID = courses.Single(c => c.Title == "Microeconomics" ).CourseID,
                Grade = Grade.C
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alexander").StudentID,
                CourseID = courses.Single(c => c.Title == "Macroeconomics" ).CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                 StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
                CourseID = courses.Single(c => c.Title == "Calculus" ).CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                 StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
                CourseID = courses.Single(c => c.Title == "Trigonometry" ).CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Alonso").StudentID,
                CourseID = courses.Single(c => c.Title == "Composition" ).CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Anand").StudentID,
                CourseID = courses.Single(c => c.Title == "Chemistry" ).CourseID
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Anand").StudentID,
                CourseID = courses.Single(c => c.Title == "Microeconomics").CourseID,
                Grade = Grade.B
             },
            new Enrollment {
                StudentID = students.Single(s => s.LastName == "Barzdukas").StudentID,
                CourseID = courses.Single(c => c.Title == "Chemistry").CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Li").StudentID,
                CourseID = courses.Single(c => c.Title == "Composition").CourseID,
                Grade = Grade.B
             },
             new Enrollment {
                StudentID = students.Single(s => s.LastName == "Justice").StudentID,
                CourseID = courses.Single(c => c.Title == "Literature").CourseID,
                Grade = Grade.B
             }
       };

    foreach (Enrollment e in enrollments)
    {
       var enrollmentInDataBase = context.Enrollments.Where(
           s =>
                s.Student.StudentID == e.StudentID &&
                s.Course.CourseID == e.CourseID).SingleOrDefault();
       if (enrollmentInDataBase == null)
       {
          context.Enrollments.Add(e);
       }
    }
    context.SaveChanges();
 }

 void AddOrUpdateInstructor(SchoolContext context, string courseTitle, string instructorName)
 {
    var crs = context.Courses.SingleOrDefault(c => c.Title == courseTitle);
```

```
            var inst = crs.Instructors.SingleOrDefault(i => i.LastName == instructorName);
            if (inst == null)
               crs.Instructors.Add(context.Instructors.Single(i => i.LastName == instructorName));
         }
      }
   }
```

As you saw in the first tutorial, most of this code simply updates or creates new entity objects and loads sample data into properties as required for testing. However, notice how the `Course` entity, which has a many-to-many relationship with the `Instructor` entity, is handled:

```
var courses = new List<Course>
{
     new Course {CourseID = 1050, Title = "Chemistry",      Credits = 3,
       Department = departments.Single( s => s.Name == "Engineering"),
       Instructors = new List<Instructor>()
     },
     ...
};
courses.ForEach(s => context.Courses.AddOrUpdate(p => p.CourseID, s));
context.SaveChanges();
```

When you create a `Course` object, you initialize the `Instructors` navigation property as an empty collection using the code `Instructors = new List<Instructor>()`. This makes it possible to add `Instructor` entities that are related to this `Course` by using the `Instructors.Add` method. If you didn't create an empty list, you wouldn't be able to add these relationships, because the `Instructors` property would be null and wouldn't have an `Add` method. You could also add the list initialization to the constructor.

Add a Migration and Update the Database

From the PMC, enter the `add-migration` command:

```
PM> add-Migration Chap4
```

If you try to update the database at this point, you'll get the following error:

The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Edit the *<timestamp>_Chap4.cs* file, and make the following code changes (you'll add a SQL statement and modify an `AddColumn` statement):

```
CreateTable(
        "dbo.CourseInstructor",
        c => new
            {
                CourseID = c.Int(nullable: false),
                InstructorID = c.Int(nullable: false),
            })
        .PrimaryKey(t => new { t.CourseID, t.InstructorID })
        .ForeignKey("dbo.Course", t => t.CourseID, cascadeDelete: true)
        .ForeignKey("dbo.Instructor", t => t.InstructorID, cascadeDelete: true)
        .Index(t => t.CourseID)
        .Index(t => t.InstructorID);

    // Create  a department for course to point to.
    Sql("INSERT INTO dbo.Department (Name, Budget, StartDate) VALUES ('Temp', 0.00, GETDATE())");
    //  default value for FK points to department created above.
    AddColumn("dbo.Course", "DepartmentID", c => c.Int(nullable: false, defaultValue: 1));
    //AddColumn("dbo.Course", "DepartmentID", c => c.Int(nullable: false));

    AlterColumn("dbo.Course", "Title", c => c.String(maxLength: 50));
    AddForeignKey("dbo.Course", "DepartmentID", "dbo.Department", "DepartmentID", cascadeDelete: true);
    CreateIndex("dbo.Course", "DepartmentID");
}

public override void Down()
{
```

(Make sure that you comment out or delete the existing `AddColumn` line when you add the new one, or you'll get an error when you enter the `update-database` command.)

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints, and that's what you're doing now. The generated code adds a non-nullable `DepartmentID` foreign key to the `Course` table. If there are already rows in the `Course` table when the code runs, the `AddColumn` operation would fail because SQL Server doesn't know what value to put in the column that can't be null. Therefore you've changed the code to give the new column a default value, and you've created a stub department named "Temp" to act as the default department. As a result, if there are existing `Course` rows when this code runs, they will all be related to the "Temp" department.

When the `Seed` method runs, it will insert rows in the `Department` table and it will relate existing `Course` rows to those new `Department` rows. If you haven't added any courses in the UI, you would then no longer need the "Temp" department or the default value on the `Course.DepartmentID` column. To allow for the possibility that someone might have added courses by using the application, you'd also want to update the `Seed` method code to ensure that all `Course` rows (not just the ones inserted by earlier runs of the `Seed` method) have valid `DepartmentID` values before you remove the default value from the column and delete the "Temp" department.

After you have finished editing the *<timestamp>_Chap4.cs* file, enter the `update-database` command in the PMC to execute the migration.

NOTE

It's possible to get other errors when migrating data and making schema changes. If you get migration errors you can't resolve, you can either change the connection string in the *Web.config* file or delete the database. The simplest approach is to rename the database in *Web.config* file. For example, change the database name to CU_test as shown in the following:

```
<add name="SchoolContext" connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=CU_Test;
      Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\CU_Test.mdf"
      providerName="System.Data.SqlClient" />
```

With a new database, there is no data to migrate, and the `update-database` command is much more likely to complete without errors. For instructions on how to delete the database, see How to Drop a Database from Visual Studio 2012.

Open the database in **Server Explorer** as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have **Server Explorer** open from the earlier time, click the **Refresh** button.)

You didn't create a model class for the `CourseInstructor` table. As explained earlier, this is a join table for the many-to-many relationship between the `Instructor` and `Course` entities.

Right-click the `CourseInstructor` table and select **Show Table Data** to verify that it has data in it as a result of the `Instructor` entities you added to the `Course.Instructors` navigation property.

CourseID	InstructorID
2021	1
2042	1
1045	2
1050	3
3141	3
1050	4
4022	5
4041	5
NULL	NULL

Summary

You now have a more complex data model and corresponding database. In the following tutorial you'll learn more about different ways to access related data.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Reading Related Data with the Entity Framework in an ASP.NET MVC Application (5 of 10)

2/20/2020 • 17 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you completed the School data model. In this tutorial you'll read and display related data — that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.

Lazy, Eager, and Explicit Loading of Related Data

There are several ways that the Entity Framework can load related data into the navigation properties of an entity:

- *Lazy loading*. When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. This results in multiple queries sent to the database — one for the entity itself and one each time that related data for the entity must be retrieved.

```
departments = context.Departments
foreach (Department d in departments)
{
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

- *Eager loading*. When the entity is read, related data is retrieved along with it. This typically results in a single join query that retrieves all of the data that's needed. You specify eager loading by using the `Include` method.

```
departments = context.Departments.Include(x => x.Courses)
foreach (Department d in departments)
{
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows and related Course rows

- *Explicit loading*. This is similar to lazy loading, except that you explicitly retrieve the related data in code; it doesn't happen automatically when you access a navigation property. You load related data manually by getting the object state manager entry for an entity and calling the `Collection.Load` method for collections or the `Reference.Load` method for properties that hold a single entity. (In the following example, if you wanted to load the Administrator navigation property, you'd replace `Collection(x => x.Courses)` with `Reference(x => x.Administrator)`.)

```
departments = context.Departments.ToList();
foreach (Department d in departments)
{
    context.Entry(d).Collection(x => x.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

Query: Course rows related to Department d

Because they don't immediately retrieve the property values, lazy loading and explicit loading are also both known as *deferred loading*.

In general, if you know you need related data for every entity retrieved, eager loading offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, in the above examples, suppose that each department has ten related courses. The eager loading example would result in just a single (join) query and a single round trip to the database. The lazy loading and explicit loading examples would both result in eleven queries and eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.

On the other hand, in some scenarios lazy loading is more efficient. Eager loading might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of entities you're processing, lazy loading might perform better because eager loading would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Typically you'd use explicit loading only when you've turned lazy loading off. One scenario when you should turn lazy loading off is during serialization. Lazy loading and serialization don't mix well, and if you aren't careful you can end up querying significantly more data than you intended when lazy loading is enabled. Serialization generally works by accessing each property on an instance of a type. Property access triggers lazy loading, and those lazy loaded entities are serialized. The serialization process then accesses each property of the lazy-loaded entities, potentially causing even more lazy loading and serialization. To prevent this run-away chain reaction, turn lazy loading off before you serialize an entity.

The database context class performs lazy loading by default. There are two ways to disable lazy loading:

- For specific navigation properties, omit the `virtual` keyword when you declare the property.
- For all navigation properties, set `LazyLoadingEnabled` to `false`. For example, you can put the following code in the constructor of your context class:

```
this.Configuration.LazyLoadingEnabled = false;
```

Lazy loading can mask code that causes performance problems. For example, code that doesn't specify eager or

explicit loading but processes a high volume of entities and uses several navigation properties in each iteration might be very inefficient (because of many round trips to the database). An application that performs well in development using an on premise SQL server might have performance problems when moved to Azure SQL Database due to the increased latency and lazy loading. Profiling the database queries with a realistic test load will help you determine if lazy loading is appropriate. For more information see Demystifying Entity Framework Strategies: Loading Related Data and Using the Entity Framework to Reduce Network Latency to SQL Azure.

Create a Courses Index Page That Displays Department Name

The `Course` entity includes a navigation property that contains the `Department` entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the `Name` property from the `Department` entity that is in the `Course.Department` navigation property.

Create a controller named `CourseController` for the `Course` entity type, using the same options that you did earlier for the `Student` controller, as shown in the following illustration (except unlike the image, your context class is in the DAL namespace, not the Models namespace):

Open *Controllers\CourseController.cs* and look at the `Index` method:

```
public ViewResult Index()
{
    var courses = db.Courses.Include(c => c.Department);
    return View(courses.ToList());
}
```

The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Open *Views\Course\Index.cshtml* and replace the existing code with the following code. The changes are highlighted:

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewBag.Title = "Courses";
}

<h2>Courses</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th></th>
        <th>Number</th>
        <th>Title</th>
        <th>Credits</th>
        <th>Department</th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.CourseID }) |
            @Html.ActionLink("Details", "Details", new { id=item.CourseID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.CourseID })
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.CourseID)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Credits)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Department.Name)
        </td>
    </tr>
}
</table>
```

You've made the following changes to the scaffolded code:

- Changed the heading from **Index** to **Courses**.
- Moved the row links to the left.
- Added a column under the heading **Number** that shows the `CourseID` property value. (By default, primary keys aren't scaffolded because normally they are meaningless to end users. However, in this case the primary key is meaningful and you want to show it.)
- Changed the last column heading from **DepartmentID** (the name of the foreign key to the `Department` entity) to **Department**.

Notice that for the last column, the scaffolded code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

```
<td>
    @Html.DisplayFor(modelItem => item.Department.Name)
</td>
```

Run the page (select the **Courses** tab on the Contoso University home page) to see the list with department

names.

Create an Instructors Index Page That Shows Courses and Enrollments

In this section you'll create a controller and view for the `Instructor` entity in order to display the Instructors Index page:

This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity. The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. You'll use eager loading for the `OfficeAssignment` entities. As explained earlier, eager loading is typically more efficient when you need the related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. You'll use eager loading for the `Course` entities and their related `Department` entities. In this case, lazy loading might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity set is displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship. You'll add explicit loading for `Enrollment` entities and their related `Student` entities. (Explicit loading isn't necessary because lazy loading is enabled, but this shows how to do explicit loading.)

Create a View Model for the Instructor Index View

The Instructor Index page shows three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

In the *ViewModels* folder, create *InstructorIndexData.cs* and replace the existing code with the following code:

```
using System.Collections.Generic;
using ContosoUniversity.Models;

namespace ContosoUniversity.ViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Adding a Style for Selected Rows

To mark selected rows you need a different background color. To provide a style for this UI, add the following highlighted code to the section `/* info and errors */` in *Content\Site.css*, as shown below:

```
/* info and errors */
.selectedrow
{
    background-color: #a4d4e6;
}
.message-info {
    border: 1px solid;
    clear: both;
    padding: 10px 20px;
}
```

Creating the Instructor Controller and Views

Create an `InstructorController` controller as shown in the following illustration:

Open *Controllers\InstructorController.cs* and add a `using` statement for the `ViewModels` namespace:

```
using ContosoUniversity.ViewModels;
```

The scaffolded code in the `Index` method specifies eager loading only for the `OfficeAssignment` navigation property:

```
public ViewResult Index()
{
    var instructors = db.Instructors.Include(i => i.OfficeAssignment);
    return View(instructors.ToList());
}
```

Replace the `Index` method with the following code to load additional related data and put it in the view model:

```
public ActionResult Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses.Select(c => c.Department))
        .OrderBy(i => i.LastName);

    if (id != null)
    {
        ViewBag.InstructorID = id.Value;
        viewModel.Courses = viewModel.Instructors.Where(
            i => i.InstructorID == id.Value).Single().Courses;
    }

    if (courseID != null)
    {
        ViewBag.CourseID = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course, and passes all of the required data to the view. The parameters are provided by the **Select** hyperlinks on the page.

TIP

Route data

Route data is data that the model binder found in a URL segment specified in the routing table. For example, the default route specifies `controller`, `action`, and `id` segments:

```
routes.MapRoute(
 name: "Default",
 url: "{controller}/{action}/{id}",
 defaults: new { controller = "Home", action = "Index", id = UrlParameter.Optional }
);
```

In the following URL, the default route maps `Instructor` as the `controller`, `Index` as the `action` and 1 as the `id`; these are route data values.

`http://localhost:1230/Instructor/Index/1?courseID=2021`

"?courseID=2021" is a query string value. The model binder will also work if you pass the `id` as a query string value:

`http://localhost:1230/Instructor/Index?id=1&CourseID=2021`

The URLs are created by `ActionLink` statements in the Razor view. In the following code, the `id` parameter matches the default route, so `id` is added to the route data.

```
@Html.ActionLink("Select", "Index", new { id = item.PersonID  })
```

In the following code, `courseID` doesn't match a parameter in the default route, so it's added as a query string.

```
@Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
```

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.Courses` navigation property.

```
var viewModel = new InstructorIndexData();
viewModel.Instructors = db.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.Courses.Select(c => c.Department))
     .OrderBy(i => i.LastName);
```

The second `Include` method loads Courses, and for each Course that is loaded it does eager loading for the `Course.Department` navigation property.

```
.Include(i => i.Courses.Select(c => c.Department))
```

As mentioned previously, eager loading is not required but is done to improve performance. Since the view always requires the `OfficeAssignment` entity, it's more efficient to fetch that in the same query. `Course` entities are required when an instructor is selected in the web page, so eager loading is better than lazy loading only if the page is displayed more often with a course selected than without.

If an instructor ID was selected, the selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the `Course` entities from that instructor's `Courses` navigation property.

```
if (id != null)
{
    ViewBag.InstructorID = id.Value;
    viewModel.Courses = viewModel.Instructors.Where(i => i.InstructorID == id.Value).Single().Courses;
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single `Instructor` entity being returned. The `Single` method converts the collection into a single `Instructor` entity, which gives you access to that entity's `Courses` property.

You use the Single method on a collection when you know the collection will have only one item. The `Single` method throws an exception if the collection passed to it is empty or if there's more than one item. An alternative is SingleOrDefault, which returns a default value (`null` in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a `null` reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the `Where` condition instead of calling the `Where` method separately:

```
.Single(i => i.InstructorID == id.Value)
```

Instead of:

```
.Where(I => i.InstructorID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the `Enrollment` entities from that course's `Enrollments` navigation property.

```
if (courseID != null)
{
    ViewBag.CourseID = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Modifying the Instructor Index View

In *Views\Instructor\Index.cshtml*, replace the existing code with the following code. The changes are highlighted:

```
@model ContosoUniversity.ViewModels.InstructorIndexData

@{
    ViewBag.Title = "Instructors";
}

<h2>Instructors</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th></th>
        <th>Last Name</th>
        <th>First Name</th>
        <th>Hire Date</th>
        <th>Office</th>
    </tr>
    @foreach (var item in Model.Instructors)
    {
        string selectedRow = "";
        if (item.InstructorID == ViewBag.InstructorID)
        {
            selectedRow = "selectedrow";
        }
        <tr class="@selectedRow" valign="top">
            <td>
                @Html.ActionLink("Select", "Index", new { id = item.InstructorID }) |
                @Html.ActionLink("Edit", "Edit", new { id = item.InstructorID }) |
                @Html.ActionLink("Details", "Details", new { id = item.InstructorID }) |
                @Html.ActionLink("Delete", "Delete", new { id = item.InstructorID })
            </td>
            <td>
                @item.LastName
            </td>
            <td>
                @item.FirstMidName
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.HireDate)
            </td>
            <td>
                @if (item.OfficeAssignment != null)
                {
                    @item.OfficeAssignment.Location
                }
            </td>
        </tr>
    }
</table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Moved the row link columns to the left.
- Removed the **FullName** column.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` is not null. (Because this is a one-to-zero-or-one relationship, there might not be a related `OfficeAssignment` entity.)

```
<td>
    @if (item.OfficeAssignment != null)
    {
        @item.OfficeAssignment.Location
    }
</td>
```

- Added code that will dynamically add `class="selectedrow"` to the `tr` element of the selected instructor. This sets a background color for the selected row using the CSS class that you created earlier. (The `valign` attribute will be useful in the following tutorial when you add a multi-row column to the table.)

```
string selectedRow = "";
if (item.InstructorID == ViewBag.InstructorID)
{
    selectedRow = "selectedrow";
}
<tr class="@selectedRow" valign="top">
```

- Added a new `ActionLink` labeled **Select** immediately before the other links in each row, which causes the selected instructor ID to be sent to the `Index` method.

Run the application and select the **Instructors** tab. The page displays the `Location` property of related `OfficeAssignment` entities and an empty table cell when there's no related `OfficeAssignment` entity.

In the *Views\Instructor\Index.cshtml* file, after the closing `table` element (at the end of the file), add the following highlighted code. This displays a list of courses related to an instructor when an instructor is selected.

```
<td>
                @if (item.OfficeAssignment != null)
                {
                    @item.OfficeAssignment.Location
                }
            </td>
        </tr>
    }
</table>

@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
<table>
    <tr>
        <th></th>
        <th>ID</th>
        <th>Title</th>
        <th>Department</th>
    </tr>

    @foreach (var item in Model.Courses)
    {
        string selectedRow = "";
        if (item.CourseID == ViewBag.CourseID)
        {
            selectedRow = "selectedrow";
        }
    <tr class="@selectedRow">
        <td>
            @Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
        </td>
        <td>
            @item.CourseID
        </td>
        <td>
            @item.Title
        </td>
        <td>
            @item.Department.Name
        </td>
    </tr>
    }

</table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a `Select` hyperlink that sends the ID of the selected course to the `Index` action method.

> **NOTE**
>
> The *.css* file is cached by browsers. If you don't see the changes when you run the application, do a hard refresh (hold down the CTRL key while clicking the **Refresh** button, or press CTRL+F5).

Run the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.

After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course</h3>
    <table>
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the `Enrollments` property of the view model in order to display a list of students enrolled in the course.

Run the page and select an instructor. Then select a course to see the list of enrolled students and their grades.

Adding Explicit Loading

Open *InstructorController.cs* and look at how the `Index` method gets the list of enrollments for a selected course:

```
if (courseID != null)
{
    ViewBag.CourseID = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
        x => x.CourseID == courseID).Single().Enrollments;
}
```

When you retrieved the list of instructors, you specified eager loading for the `Courses` navigation property and for the `Department` property of each course. Then you put the `Courses` collection in the view model, and now you're accessing the `Enrollments` navigation property from one entity in that collection. Because you didn't specify eager loading for the `Course.Enrollments` navigation property, the data from that property is appearing in the page as a result of lazy loading.

If you disabled lazy loading without changing the code in any other way, the `Enrollments` property would be null regardless of how many enrollments the course actually had. In that case, to load the `Enrollments` property, you'd have to specify either eager loading or explicit loading. You've already seen how to do eager loading. In order to see an example of explicit loading, replace the `Index` method with the following code, which explicitly loads the `Enrollments` property. The code changed are highlighted.

```
public ActionResult Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();

    viewModel.Instructors = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses.Select(c => c.Department))
        .OrderBy(i => i.LastName);

    if (id != null)
    {
        ViewBag.InstructorID = id.Value;
        viewModel.Courses = viewModel.Instructors.Where(
            i => i.InstructorID == id.Value).Single().Courses;
    }

    if (courseID != null)
    {
        ViewBag.CourseID = courseID.Value;
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID == courseID).Single();
        db.Entry(selectedCourse).Collection(x => x.Enrollments).Load();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            db.Entry(enrollment).Reference(x => x.Student).Load();
        }

        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

After getting the selected `Course` entity, the new code explicitly loads that course's `Enrollments` navigation property:

```
db.Entry(selectedCourse).Collection(x => x.Enrollments).Load();
```

Then it explicitly loads each `Enrollment` entity's related `Student` entity:

```
db.Entry(enrollment).Reference(x => x.Student).Load();
```

Notice that you use the `Collection` method to load a collection property, but for a property that holds just one entity, you use the `Reference` method. You can run the Instructor Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Summary

You've now used all three ways (lazy, eager, and explicit) to load related data into navigation properties. In the next tutorial you'll learn how to update related data.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Updating Related Data with the Entity Framework in an ASP.NET MVC Application (6 of 10)

2/20/2020 • 16 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you displayed related data; in this tutorial you'll update related data. For most relationships, this can be done by updating the appropriate foreign key fields. For many-to-many relationships, the Entity Framework doesn't expose the join table directly, so you must explicitly add and remove entities to and from the appropriate navigation properties.

The following illustrations show the pages that you'll work with.

Customize the Create and Edit Pages for Courses

When a new course entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate `Department` entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In *CourseController.cs*, delete the four `Edit` and `Create` methods and replace them with the following code:

```
public ActionResult Create()
{
   PopulateDepartmentsDropDownList();
   return View();
}

[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Create(
   [Bind(Include = "CourseID,Title,Credits,DepartmentID")]
   Course course)
{
```

```
    try
    {
       if (ModelState.IsValid)
       {
          db.Courses.Add(course);
          db.SaveChanges();
          return RedirectToAction("Index");
       }
    }
    catch (DataException /* dex */)
    {
       //Log the error (uncomment dex variable name after DataException and add a line here to write a log.)
       ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see your
system administrator.");
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}

public ActionResult Edit(int id)
{
    Course course = db.Courses.Find(id);
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}

[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(
     [Bind(Include = "CourseID,Title,Credits,DepartmentID")]
     Course course)
{
    try
    {
       if (ModelState.IsValid)
       {
          db.Entry(course).State = EntityState.Modified;
          db.SaveChanges();
          return RedirectToAction("Index");
       }
    }
    catch (DataException /* dex */)
    {
       //Log the error (uncomment dex variable name after DataException and add a line here to write a log.)
       ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see your
system administrator.");
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}

private void PopulateDepartmentsDropDownList(object selectedDepartment = null)
{
    var departmentsQuery = from d in db.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery, "DepartmentID", "Name", selectedDepartment);
}
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in a `ViewBag` property. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name `DepartmentID` to the `DropDownList` helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named `DepartmentID`.

The `HttpGet` `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item,

because for a new course the department is not established yet:

```
public ActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The `HttpGet` `Edit` method sets the selected item, based on the ID of the department that is already assigned to the course being edited:

```
public ActionResult Edit(int id)
{
    Course course = db.Courses.Find(id);
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The `HttpPost` methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error:

```
catch (DataException /* dex */)
{
    //Log the error (uncomment dex variable name after DataException and add a line here to write a log.)
    ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see your
system administrator.");
}
PopulateDepartmentsDropDownList(course.DepartmentID);
return View(course);
```

This code ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

In *Views\Course\Create.cshtml*, add the highlighted code to create a new course number field before the **Title** field. As explained in an earlier tutorial, primary key fields aren't scaffolded by default, but this primary key is meaningful, so you want the user to be able to enter the key value.

```
@model ContosoUniversity.Models.Course

@{
    ViewBag.Title = "Create";
}

<h2>Create</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()
    @Html.ValidationSummary(true)

    <fieldset>
        <legend>Course</legend>

        <div class="editor-label">
            @Html.LabelFor(model => model.CourseID)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.CourseID)
            @Html.ValidationMessageFor(model => model.CourseID)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Title)
            @Html.ValidationMessageFor(model => model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Credits)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Credits)
            @Html.ValidationMessageFor(model => model.Credits)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.DepartmentID, "Department")
        </div>
        <div class="editor-field">
            @Html.DropDownList("DepartmentID", String.Empty)
            @Html.ValidationMessageFor(model => model.DepartmentID)
        </div>

        <p>
            <input type="submit" value="Create" />
        </p>
    </fieldset>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

In *Views\Course\Edit.cshtml*, *Views\Course\Delete.cshtml*, and *Views\Course\Details.cshtml*, add a course number field before the **Title** field. Because it's the primary key, it's displayed, but it can't be changed.

```
<div class="editor-label">
    @Html.LabelFor(model => model.CourseID)
</div>
<div class="editor-field">
    @Html.DisplayFor(model => model.CourseID)
</div>
```

Run the **Create** page (display the Course Index page and click **Create New**) and enter data for a new course:

Click **Create**. The Course Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Run the **Edit** page (display the Course Index page and click **Edit** on a course).

Change data on the page and click **Save**. The Course Index page is displayed with the updated course data.

Adding an Edit Page for Instructors

When you edit an instructor record, you want to be able to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity, which means you must handle the following situations:

- If the user clears the office assignment and it originally had a value, you must remove and delete the `OfficeAssignment` entity.
- If the user enters an office assignment value and it originally was empty, you must create a new `OfficeAssignment` entity.
- If the user changes the value of an office assignment, you must change the value in an existing `OfficeAssignment` entity.

Open *InstructorController.cs* and look at the `HttpGet` `Edit` method:

```
public ActionResult Edit(int id = 0)
{
    Instructor instructor = db.Instructors.Find(id);
    if (instructor == null)
    {
        return HttpNotFound();
    }
    ViewBag.InstructorID = new SelectList(db.OfficeAssignments, "InstructorID", "Location",
instructor.InstructorID);
    return View(instructor);
}
```

The scaffolded code here isn't what you want. It's setting up data for a drop-down list, but you what you need is a text box. Replace this method with the following code:

```
public ActionResult Edit(int id)
{
    Instructor instructor = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Where(i => i.InstructorID == id)
        .Single();
    return View(instructor);
}
```

This code drops the `ViewBag` statement and adds eager loading for the associated `OfficeAssignment` entity. You can't perform eager loading with the `Find` method, so the `Where` and `Single` methods are used instead to select the instructor.

Replace the `HttpPost` `Edit` method with the following code. which handles office assignment updates:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(int id, FormCollection formCollection)
{
   var instructorToUpdate = db.Instructors
       .Include(i => i.OfficeAssignment)
       .Where(i => i.InstructorID == id)
       .Single();

   if (TryUpdateModel(instructorToUpdate, "",
      new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
   {
      try
      {
         if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
         {
            instructorToUpdate.OfficeAssignment = null;
         }

         db.Entry(instructorToUpdate).State = EntityState.Modified;
         db.SaveChanges();

         return RedirectToAction("Index");
      }
      catch (DataException /* dex */)
      {
         //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
         ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
      }
   }
   ViewBag.InstructorID = new SelectList(db.OfficeAssignments, "InstructorID", "Location", id);
   return View(instructorToUpdate);
}
```

The code does the following:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property. This is the same as what you did in the `HttpGet` `Edit` method.
- Updates the retrieved `Instructor` entity with values from the model binder. The TryUpdateModel overload used enables you to *whitelist* the properties you want to include. This prevents over-posting, as explained in the second tutorial.

  ```
  if (TryUpdateModel(instructorToUpdate, "",
        new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
  ```

- If the office location is blank, sets the `Instructor.OfficeAssignment` property to null so that the related row in the `OfficeAssignment` table will be deleted.

  ```
  if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
  {
      instructorToUpdate.OfficeAssignment = null;
  }
  ```

- Saves the changes to the database.

In *Views\Instructor\Edit.cshtml*, after the `div` elements for the **Hire Date** field, add a new field for editing the office location:

```
<div class="editor-label">
    @Html.LabelFor(model => model.OfficeAssignment.Location)
</div>
<div class="editor-field">
    @Html.EditorFor(model => model.OfficeAssignment.Location)
    @Html.ValidationMessageFor(model => model.OfficeAssignment.Location)
</div>
```

Run the page (select the **Instructors** tab and then click **Edit** on an instructor). Change the **Office Location** and click **Save**.

Adding Course Assignments to the Instructor Edit Page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of check boxes, as shown in the following screen shot:

The relationship between the `Course` and `Instructor` entities is many-to-many, which means you do not have direct access to the join table. Instead, you will add and remove entities to and from the `Instructor.Courses` navigation property.

The UI that enables you to change which courses an instructor is assigned to is a group of check boxes. A check box for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear check boxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating navigation properties in order to create or delete relationships.

To provide data to the view for the list of check boxes, you'll use a view model class. Create *AssignedCourseData.cs* in the *ViewModels* folder and replace the existing code with the following code:

```
namespace ContosoUniversity.ViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In *InstructorController.cs*, replace the `HttpGet` `Edit` method with the following code. The changes are highlighted.

```
public ActionResult Edit(int id)
{
    Instructor instructor = db.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.Courses)
        .Where(i => i.InstructorID == id)
        .Single();
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
    var allCourses = db.Courses;
    var instructorCourses = new HashSet<int>(instructor.Courses.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewBag.Courses = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the check box array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all `Course` entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a HashSet collection. The `Assigned` property is set to `true` for courses the instructor is assigned. The view will use this property to determine which check boxes must be displayed as selected. Finally, the list is passed to the view in a `ViewBag` property.

Next, add the code that's executed when the user clicks **Save**. Replace the `HttpPost` `Edit` method with the following code, which calls a new method that updates the `Courses` navigation property of the `Instructor` entity. The changes are highlighted.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(int id, FormCollection formCollection, string[] selectedCourses)
{
   var instructorToUpdate = db.Instructors
       .Include(i => i.OfficeAssignment)
       .Include(i => i.Courses)
       .Where(i => i.InstructorID == id)
       .Single();
   if (TryUpdateModel(instructorToUpdate, "",
      new string[] { "LastName", "FirstMidName", "HireDate", "OfficeAssignment" }))
   {
      try
      {
         if (String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment.Location))
         {
            instructorToUpdate.OfficeAssignment = null;
         }

         UpdateInstructorCourses(selectedCourses, instructorToUpdate);

         db.Entry(instructorToUpdate).State = EntityState.Modified;
         db.SaveChanges();

         return RedirectToAction("Index");
      }
      catch (DataException /* dex */)
      {
         //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
         ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists see your
system administrator.");
      }
   }
   PopulateAssignedCourseData(instructorToUpdate);
   return View(instructorToUpdate);
}

private void UpdateInstructorCourses(string[] selectedCourses, Instructor instructorToUpdate)
{
   if (selectedCourses == null)
   {
      instructorToUpdate.Courses = new List<Course>();
      return;
   }

   var selectedCoursesHS = new HashSet<string>(selectedCourses);
   var instructorCourses = new HashSet<int>
       (instructorToUpdate.Courses.Select(c => c.CourseID));
   foreach (var course in db.Courses)
   {
      if (selectedCoursesHS.Contains(course.CourseID.ToString()))
      {
         if (!instructorCourses.Contains(course.CourseID))
         {
            instructorToUpdate.Courses.Add(course);
         }
      }
      else
      {
         if (instructorCourses.Contains(course.CourseID))
         {
            instructorToUpdate.Courses.Remove(course);
         }
      }
   }
}
```

Since the view doesn't have a collection of `Course` entities, the model binder can't automatically update the `Courses` navigation property. Instead of using the model binder to update the Courses navigation property, you'll do that in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `Courses` property from model binding. This doesn't require any change to the code that calls TryUpdateModel because you're using the *whitelisting* overload and `Courses` isn't in the include list.

If no check boxes were selected, the code in `UpdateInstructorCourses` initializes the `Courses` navigation property with an empty collection:

```
if (selectedCourses == null)
{
    instructorToUpdate.Courses = new List<Course>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the check box for a course was selected but the course isn't in the `Instructor.Courses` navigation property, the course is added to the collection in the navigation property.

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Add(course);
    }
}
```

If the check box for a course wasn't selected, but the course is in the `Instructor.Courses` navigation property, the course is removed from the navigation property.

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Remove(course);
    }
}
```

In *Views\Instructor\Edit.cshtml*, add a **Courses** field with an array of check boxes by adding the following highlighted code immediately after the `div` elements for the `OfficeAssignment` field:

```
@model ContosoUniversity.Models.Instructor

@{
    ViewBag.Title = "Edit";
}

<h2>Edit</h2>

@using (Html.BeginForm())
{
    @Html.AntiForgeryToken()
    @Html.ValidationSummary(true)

    <fieldset>
        <legend>Instructor</legend>
```

```
        @Html.HiddenFor(model => model.InstructorID)

        <div class="editor-label">
            @Html.LabelFor(model => model.LastName)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.LastName)
            @Html.ValidationMessageFor(model => model.LastName)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.FirstMidName)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.FirstMidName)
            @Html.ValidationMessageFor(model => model.FirstMidName)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.HireDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.HireDate)
            @Html.ValidationMessageFor(model => model.HireDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.OfficeAssignment.Location)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.OfficeAssignment.Location)
            @Html.ValidationMessageFor(model => model.OfficeAssignment.Location)
        </div>

        <div class="editor-field">
    <table>
        <tr>
            @{
                int cnt = 0;
                List<ContosoUniversity.ViewModels.AssignedCourseData> courses = ViewBag.Courses;

                foreach (var course in courses) {
                    if (cnt++ % 3 == 0) {
                        @:  </tr> <tr>
                    }
                    @: <td>
                        <input type="checkbox"
                               name="selectedCourses"
                               value="@course.CourseID"
                               @(Html.Raw(course.Assigned ? "checked=\"checked\"" : "")) />
                        @course.CourseID @:  @course.Title
                    @:</td>
                }
                @: </tr>
            }
    </table>
</div>
        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>

@section Scripts {
```

```
@section Scripts {
    @Scripts.Render("~/bundles/jqueryval")
}
```

This code creates an HTML table that has three columns. In each column is a check box followed by a caption that consists of the course number and title. The check boxes all have the same name ("selectedCourses"), which informs the model binder that they are to be treated as a group. The `value` attribute of each check box is set to the value of `CourseID.` When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the check boxes which are selected.

When the check boxes are initially rendered, those that are for courses assigned to the instructor have `checked` attributes, which selects them (displays them checked).

After changing course assignments, you'll want to be able to verify the changes when the site returns to the `Index` page. Therefore, you need to add a column to the table in that page. In this case you don't need to use the `ViewBag` object, because the information you want to display is already in the `Courses` navigation property of the `Instructor` entity that you're passing to the page as the model.

In *Views\Instructor\Index.cshtml*, add a **Courses** heading immediately following the **Office** heading, as shown in the following example:

```
<tr>
    <th></th>
    <th>Last Name</th>
    <th>First Name</th>
    <th>Hire Date</th>
    <th>Office</th>
    <th>Courses</th>
</tr>
```

Then add a new detail cell immediately following the office location detail cell:

```
@model ContosoUniversity.ViewModels.InstructorIndexData

@{
    ViewBag.Title = "Instructors";
}

<h2>Instructors</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th></th>
        <th>Last Name</th>
        <th>First Name</th>
        <th>Hire Date</th>
        <th>Office</th>
        <th>Courses</th>
    </tr>
    @foreach (var item in Model.Instructors)
    {
        string selectedRow = "";
        if (item.InstructorID == ViewBag.InstructorID)
        {
            selectedRow = "selectedrow";
        }
        <tr class="@selectedRow" valign="top">
            <td>
                @Html.ActionLink("Select", "Index", new { id = item.InstructorID }) |
                @Html.ActionLink("Edit", "Edit", new { id = item.InstructorID }) |
```

```
                @Html.ActionLink("Edit", "Edit", new { id = item.InstructorID }) |
                @Html.ActionLink("Details", "Details", new { id = item.InstructorID }) |
                @Html.ActionLink("Delete", "Delete", new { id = item.InstructorID })
            </td>
            <td>
                @item.LastName
            </td>
            <td>
                @item.FirstMidName
            </td>
            <td>
                @String.Format("{0:d}", item.HireDate)
            </td>
            <td>
                @if (item.OfficeAssignment != null)
                {
                    @item.OfficeAssignment.Location
                }
            </td>
            <td>
                @{
                foreach (var course in item.Courses)
                {
                    @course.CourseID @:  @course.Title <br />
                }
                }
            </td>
        </tr>
    }
</table>

@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table>
        <tr>
            <th></th>
            <th>ID</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == ViewBag.CourseID)
            {
                selectedRow = "selectedrow";
            }

            <tr class="@selectedRow">

                <td>
                    @Html.ActionLink("Select", "Index", new { courseID = item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

```
@if (Model.Enrollments != null)
{
    <h3>Students Enrolled in Selected Course</h3>
    <table>
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

Run the **Instructor Index** page to see the courses assigned to each instructor:

Click **Edit** on an instructor to see the Edit page.

Change some course assignments and click **Save**. The changes you make are reflected on the Index page.

Note: The approach taken to edit instructor course data works well when there is a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update the Delete Method

Change the code in the HttpPost Delete method so the office assignment record (if any) is deleted when the instructor is deleted:

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public ActionResult DeleteConfirmed(int id)
{
   Instructor instructor = db.Instructors
     .Include(i => i.OfficeAssignment)
     .Where(i => i.InstructorID == id)
     .Single();

   instructor.OfficeAssignment = null;
   db.Instructors.Remove(instructor);
   db.SaveChanges();
   return RedirectToAction("Index");
}
```

If you try to delete an instructor who is assigned to a department as administrator, you'll get a referential integrity error. See the current version of this tutorial for additional code that will automatically remove the instructor from any department where the instructor is assigned as an administrator.

Summary

You have now completed this introduction to working with related data. So far in these tutorials you've done a full range of CRUD operations, but you haven't dealt with concurrency issues. The next tutorial will introduce the topic of concurrency, explain options for handling it, and add concurrency handling to the CRUD code you've already written for one entity type.

Links to other Entity Framework resources, can be found at the end of the last tutorial in this series.

Handling Concurrency with the Entity Framework in an ASP.NET MVC Application (7 of 10)

2/21/2020 • 16 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous two tutorials you worked with related data. This tutorial shows how to handle concurrency. You'll create web pages that work with the `Department` entity, and the pages that edit and delete `Department` entities will handle concurrency errors. The following illustrations show the Index and Delete pages, including some messages that are displayed if a concurrency conflict occurs.

Concurrency Conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.

Pessimistic Concurrency (Locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called *pessimistic concurrency*. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.

Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases (that is, it

doesn't scale well). For these reasons, not all database management systems support pessimistic concurrency. The Entity Framework provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency

The alternative to pessimistic concurrency is *optimistic concurrency*. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, John runs the Departments Edit page, changes the **Budget** amount for the English department from $350,000.00 to $0.00.

Before John clicks **Save**, Jane runs the same page and changes the **Start Date** field from 9/1/2007 to 8/8/2013.

John clicks **Save** first and sees his change when the browser returns to the Index page, then Jane clicks **Save**. What happens next is determined by how you handle concurrency conflicts. Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database. In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they'll see both John's and Jane's changes — a start date of 8/8/2013 and a budget of Zero dollars.

  This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are made to the same property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields).

- You can let Jane's change overwrite John's change. The next time someone browses the English department, they'll see 8/8/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (The client's values take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent Jane's change from being updated in the database. Typically, you would display an error message, show her the current state of the data, and allow her to reapply her changes if she still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that

no changes are overwritten without a user being alerted to what's happening.

Detecting Concurrency Conflicts

You can resolve conflicts by handling OptimisticConcurrencyException exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the `Where` clause of SQL `Update` or `Delete` commands.

  The data type of the tracking column is typically rowversion. The rowversion value is a sequential number that's incremented each time the row is updated. In an `Update` or `Delete` command, the `Where` clause includes the original value of the tracking column (the original row version). If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the `Update` or `Delete` statement can't find the row to update because of the `Where` clause. When the Entity Framework finds that no rows have been updated by the `Update` or `Delete` command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the `Where` clause of `Update` and `Delete` commands.

  As in the first option, if anything in the row has changed since the row was first read, the `Where` clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large `Where` clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself. Therefore this approach generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the ConcurrencyCheck attribute to them. That change enables the Entity Framework to include all columns in the SQL `WHERE` clause of `UPDATE` statements.

In the remainder of this tutorial you'll add a rowversion tracking property to the `Department` entity, create a controller and views, and test to verify that everything works correctly.

Add an Optimistic Concurrency Property to the Department Entity

In *Models\Department.cs*, add a tracking property named `RowVersion`:

```
public class Department
{
    public int DepartmentID { get; set; }

    [StringLength(50, MinimumLength = 3)]
    public string Name { get; set; }

    [DataType(DataType.Currency)]
    [Column(TypeName = "money")]
    public decimal Budget { get; set; }

    [DataType(DataType.Date)]
    public DateTime StartDate { get; set; }

    [Display(Name = "Administrator")]
    public int? InstructorID { get; set; }

    [Timestamp]
    public byte[] RowVersion { get; set; }

    public virtual Instructor Administrator { get; set; }
    public virtual ICollection<Course> Courses { get; set; }
}
```

The Timestamp attribute specifies that this column will be included in the `Where` clause of `Update` and `Delete` commands sent to the database. The attribute is called Timestamp because previous versions of SQL Server used a SQL timestamp data type before the SQL rowversion replaced it. The .Net type for `rowversion` is a byte array. If you prefer to use the fluent API, you can use the IsConcurrencyToken method to specify the tracking property, as shown in the following example:

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsConcurrencyToken();
```

See the GitHub issue Replace IsConcurrencyToken by IsRowVersion.

By adding a property you changed the database model, so you need to do another migration. In the Package Manager Console (PMC), enter the following commands:

```
Add-Migration RowVersion
Update-Database
```

Create a Department Controller

Create a `Department` controller and views the same way you did the other controllers, using the following settings:

In *Controllers\DepartmentController.cs*, add a `using` statement:

```
using System.Data.Entity.Infrastructure;
```

Change "LastName" to "FullName" everywhere in this file (four occurrences) so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

```
ViewBag.InstructorID = new SelectList(db.Instructors, "InstructorID", "FullName");
```

Replace the existing code for the `HttpPost` `Edit` method with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(
   [Bind(Include = "DepartmentID, Name, Budget, StartDate, RowVersion, InstructorID")]
    Department department)
{
   try
   {
      if (ModelState.IsValid)
      {
         db.Entry(department).State = EntityState.Modified;
         db.SaveChanges();
         return RedirectToAction("Index");
      }
   }
   catch (DbUpdateConcurrencyException ex)
   {
      var entry = ex.Entries.Single();
      var clientValues = (Department)entry.Entity;
      var databaseValues = (Department)entry.GetDatabaseValues().ToObject();

      if (databaseValues.Name != clientValues.Name)
         ModelState.AddModelError("Name", "Current value: "
             + databaseValues.Name);
      if (databaseValues.Budget != clientValues.Budget)
         ModelState.AddModelError("Budget", "Current value: "
             + String.Format("{0:c}", databaseValues.Budget));
      if (databaseValues.StartDate != clientValues.StartDate)
         ModelState.AddModelError("StartDate", "Current value: "
             + String.Format("{0:d}", databaseValues.StartDate));
      if (databaseValues.InstructorID != clientValues.InstructorID)
         ModelState.AddModelError("InstructorID", "Current value: "
             + db.Instructors.Find(databaseValues.InstructorID).FullName);
      ModelState.AddModelError(string.Empty, "The record you attempted to edit "
          + "was modified by another user after you got the original value. The "
          + "edit operation was canceled and the current values in the database "
          + "have been displayed. If you still want to edit this record, click "
          + "the Save button again. Otherwise click the Back to List hyperlink.");
      department.RowVersion = databaseValues.RowVersion;
   }
   catch (DataException /* dex */)
   {
      //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
      ModelState.AddModelError(string.Empty, "Unable to save changes. Try again, and if the problem persists
contact your system administrator.");
   }

   ViewBag.InstructorID = new SelectList(db.Instructors, "InstructorID", "FullName", department.InstructorID);
   return View(department);
}
```

The view will store the original `RowVersion` value in a hidden field. When the model binder creates the `department` instance, that object will have the original `RowVersion` property value and the new values for the other properties, as entered by the user on the Edit page. Then when the Entity Framework creates a SQL `UPDATE` command, that command will include a `WHERE` clause that looks for a row that has the original `RowVersion` value.

If no rows are affected by the `UPDATE` command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception, and the code in the `catch` block gets the affected `Department` entity from the exception object. This entity has both the values read from the database and the new values entered by the user:

```
var entry = ex.Entries.Single();
var clientValues = (Department)entry.Entity;
var databaseValues = (Department)entry.GetDatabaseValues().ToObject();
```

Next, the code adds a custom error message for each column that has database values different from what the user entered on the Edit page:

```
if (databaseValues.Name != currentValues.Name)
    ModelState.AddModelError("Name", "Current value: " + databaseValues.Name);
    // ...
```

A longer error message explains what happened and what to do about it:

```
ModelState.AddModelError(string.Empty, "The record you attempted to edit "
    + "was modified by another user after you got the original value. The"
    + "edit operation was canceled and the current values in the database "
    + "have been displayed. If you still want to edit this record, click "
    + "the Save button again. Otherwise click the Back to List hyperlink.");
```

Finally, the code sets the `RowVersion` value of the `Department` object to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

In *Views\Department\Edit.cshtml*, add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property:

```
@model ContosoUniversity.Models.Department

@{
    ViewBag.Title = "Edit";
}

<h2>Edit</h2>

@using (Html.BeginForm()) {
    @Html.AntiForgeryToken()
    @Html.ValidationSummary(true)

    <fieldset>
        <legend>Department</legend>

        @Html.HiddenFor(model => model.DepartmentID)
        @Html.HiddenFor(model => model.RowVersion)

        <div class="editor-label">
            @Html.LabelFor(model => model.Name)
        </div>
```

In *Views\Department\Index.cshtml*, replace the existing code with the following code to move row links to the left and change the page title and column headings to display `FullName` instead of `LastName` in the **Administrator** column:

```
@model IEnumerable<ContosoUniversity.Models.Department>

@{
    ViewBag.Title = "Departments";
}

<h2>Departments</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th></th>
        <th>Name</th>
        <th>Budget</th>
        <th>Start Date</th>
        <th>Administrator</th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.DepartmentID }) |
            @Html.ActionLink("Details", "Details", new { id=item.DepartmentID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.DepartmentID })
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Budget)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.StartDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Administrator.FullName)
        </td>
    </tr>
}

</table>
```

Testing Optimistic Concurrency Handling

Run the site and click **Departments**:

Right click the **Edit** hyperlink for Kim Abercrombie and select **Open in new tab**, then click the **Edit** hyperlink for Kim Abercrombie. The two windows display the same information.

Change a field in the first browser window and click **Save**.

The browser shows the Index page with the changed value.

Change the any field in the second browser window and click **Save**.

Click **Save** in the second browser window. You see an error message:

Click **Save** again. The value you entered in the second browser is saved along with the original value of the data you change in the first browser. You see the saved values when the Index page appears.

Updating the Delete Page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the `HttpGet` `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the `HttpPost` `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL `DELETE` command, it includes a `WHERE` clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the `HttpGet Delete` method is called with an error flag set to `true` in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case a different error message is displayed.

In *DepartmentController.cs*, replace the `HttpGet` `Delete` method with the following code:

```
public ActionResult Delete(int id, bool? concurrencyError)
{
    Department department = db.Departments.Find(id);

    if (concurrencyError.GetValueOrDefault())
    {
        if (department == null)
        {
            ViewBag.ConcurrencyErrorMessage = "The record you attempted to delete "
                + "was deleted by another user after you got the original values. "
                + "Click the Back to List hyperlink.";
        }
        else
        {
            ViewBag.ConcurrencyErrorMessage = "The record you attempted to delete "
                + "was modified by another user after you got the original values. "
                + "The delete operation was canceled and the current values in the "
                + "database have been displayed. If you still want to delete this "
                + "record, click the Delete button again. Otherwise "
                + "click the Back to List hyperlink.";
        }
    }

    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is `true`, an error message is sent to the view using a `ViewBag` property.

Replace the code in the `HttpPost` `Delete` method (named `DeleteConfirmed`) with the following code:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Delete(Department department)
{
    try
    {
        db.Entry(department).State = EntityState.Deleted;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    catch (DbUpdateConcurrencyException)
    {
        return RedirectToAction("Delete", new { concurrencyError=true } );
    }
    catch (DataException /* dex */)
    {
        //Log the error (uncomment dex variable name after DataException and add a line here to write a log.
        ModelState.AddModelError(string.Empty, "Unable to delete. Try again, and if the problem persists
contact your system administrator.");
        return View(department);
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

```
public ActionResult DeleteConfirmed(int id)
```

You've changed this parameter to a `Department` entity instance created by the model binder. This gives you access to the `RowVersion` property value in addition to the record key.

```
public ActionResult Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code named the `HttpPost` `Delete` method `DeleteConfirmed` to give the `HttpPost` method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the `HttpPost` and `HttpGet` delete methods.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

In *Views\Department\Delete.cshtml*, replace the scaffolded code with the following code that makes some formatting changes and adds an error message field. The changes are highlighted.

```
@model ContosoUniversity.Models.Department

@{
    ViewBag.Title = "Delete";
}

<h2>Delete</h2>

<p class="error">@ViewBag.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<fieldset>
    <legend>Department</legend>

    <div class="display-label">
         @Html.DisplayNameFor(model => model.Name)
    </div>
    <div class="display-field">
        @Html.DisplayFor(model => model.Name)
    </div>

    <div class="display-label">
         @Html.DisplayNameFor(model => model.Budget)
    </div>
    <div class="display-field">
        @Html.DisplayFor(model => model.Budget)
    </div>

    <div class="display-label">
         @Html.DisplayNameFor(model => model.StartDate)
    </div>
    <div class="display-field">
        @Html.DisplayFor(model => model.StartDate)
    </div>

    <div class="display-label">
         @Html.DisplayNameFor(model => model.Administrator.FullName)
    </div>
    <div class="display-field">
        @Html.DisplayFor(model => model.Administrator.FullName)
    </div>
</fieldset>
@using (Html.BeginForm()) {
    @Html.AntiForgeryToken()
   @Html.HiddenFor(model => model.DepartmentID)
    @Html.HiddenFor(model => model.RowVersion)
    <p>
        <input type="submit" value="Delete" /> |
        @Html.ActionLink("Back to List", "Index")
    </p>
}
```

This code adds an error message between the `h2` and `h3` headings:

```
<p class="error">@ViewBag.ConcurrencyErrorMessage</p>
```

It replaces `LastName` with `FullName` in the `Administrator` field:

```
<div class="display-label">
    @Html.LabelFor(model => model.InstructorID)
</div>
<div class="display-field">
    @Html.DisplayFor(model => model.Administrator.FullName)
</div>
```

Finally, it adds hidden fields for the `DepartmentID` and `RowVersion` properties after the `Html.BeginForm` statement:

```
@Html.HiddenFor(model => model.DepartmentID)
@Html.HiddenFor(model => model.RowVersion)
```

Run the Departments Index page. Right click the **Delete** hyperlink for the English department and select **Open in new window,** then in the first window click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save** :

The Index page confirms the change.

In the second window, click **Delete**.

You see the concurrency error message, and the Department values are refreshed with what's currently in the database.

If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Summary

This completes the introduction to handling concurrency conflicts. For information about other ways to handle various concurrency scenarios, see Optimistic Concurrency Patterns and Working with Property Values on the Entity Framework team blog. The next tutorial shows how to implement table-per-hierarchy inheritance for the `Instructor` and `Student` entities.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Implementing Inheritance with the Entity Framework in an ASP.NET MVC Application (8 of 10)

2/20/2020 • 9 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

In object-oriented programming, you can use inheritance to eliminate redundant code. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

Table-per-Hierarchy versus Table-per-Type Inheritance

In object-oriented programming, you can use inheritance to make it easier to work with related classes. For example, the `Instructor` and `Student` classes in the `School` data model share several properties, which results in redundant code:

Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. You could create a `Person` base class which contains only those shared properties, then make the `Instructor` and `Student` entities inherit from that base class, as shown in the following illustration:

There are several ways this inheritance structure could be represented in the database. You could have a `Person` table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (`HireDate`), some only to students (`EnrollmentDate`), some to both (`LastName`, `FirstName`). Typically, you'd have a *discriminator* column to indicate which type each row represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.

This pattern of generating an entity inheritance structure from a single database table is called *table-per-hierarchy* (TPH) inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the `Person` table and have separate `Instructor` and `Student` tables with the date fields.

This pattern of making a database table for each entity class is called *table per type* (TPT) inheritance.

TPH inheritance patterns generally deliver better performance in the Entity Framework than TPT inheritance

patterns, because TPT patterns can result in complex join queries. This tutorial demonstrates how to implement TPH inheritance. You'll do that by performing the following steps:

- Create a `Person` class and change the `Instructor` and `Student` classes to derive from `Person`.
- Add model-to-database mapping code to the database context class.
- Change `InstructorID` and `StudentID` references throughout the project to `PersonID`.

Creating the Person Class

Note: You won't be able to compile the project after creating the classes below until you update the controllers that uses these classes.

In the *Models* folder, create *Person.cs* and replace the template code with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
   public abstract class Person
   {
      [Key]
      public int PersonID { get; set; }

      [RegularExpression(@"^[A-Z]+[a-zA-Z""'\s-]*$")]
      [StringLength(50, MinimumLength = 1)]
      [Display(Name = "Last Name")]
      public string LastName { get; set; }

      [Column("FirstName")]
      [Display(Name = "First Name")]
      [StringLength(50, MinimumLength = 2, ErrorMessage = "First name must be between 2 and 50 characters.")]
      public string FirstMidName { get; set; }

      public string FullName
      {
         get
         {
            return LastName + ", " + FirstMidName;
         }
      }
   }
}
```

In *Instructor.cs*, derive the `Instructor` class from the `Person` class and remove the key and name fields. The code will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public virtual ICollection<Course> Courses { get; set; }
        public virtual OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make similar changes to *Student.cs*. The `Student` class will look like the following example:

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public virtual ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Adding the Person Entity Type to the Model

In *SchoolContext.cs*, add a `DbSet` property for the `Person` entity type:

```
public DbSet<Person> People { get; set; }
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is re-created, it will have a `Person` table in place of the `Student` and `Instructor` tables.

Changing InstructorID and StudentID to PersonID

In *SchoolContext.cs*, in the Instructor-Course mapping statement, change `MapRightKey("InstructorID")` to `MapRightKey("PersonID")`:

```
modelBuilder.Entity<Course>()
    .HasMany(c => c.Instructors).WithMany(i => i.Courses)
    .Map(t => t.MapLeftKey("CourseID")
    .MapRightKey("PersonID")
    .ToTable("CourseInstructor"));
```

This change isn't required; it just changes the name of the InstructorID column in the many-to-many join table. If you left the name as InstructorID, the application would still work correctly. Here is the completed

SchoolContext.cs:

```
using ContosoUniversity.Models;
using System.Data.Entity;
using System.Data.Entity.ModelConfiguration.Conventions;

namespace ContosoUniversity.DAL
{
   public class SchoolContext : DbContext
   {
      public DbSet<Course> Courses { get; set; }
      public DbSet<Department> Departments { get; set; }
      public DbSet<Enrollment> Enrollments { get; set; }
      public DbSet<Instructor> Instructors { get; set; }
      public DbSet<Student> Students { get; set; }
      public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
      public DbSet<Person> People { get; set; }

      protected override void OnModelCreating(DbModelBuilder modelBuilder)
      {
         modelBuilder.Conventions.Remove<PluralizingTableNameConvention>();

         modelBuilder.Entity<Course>()
             .HasMany(c => c.Instructors).WithMany(i => i.Courses)
             .Map(t => t.MapLeftKey("CourseID")
                 .MapRightKey("PersonID")
                 .ToTable("CourseInstructor"));
      }
   }
}
```

Next you need to change `InstructorID` to `PersonID` and `StudentID` to `PersonID` throughout the project ***except*** in the time-stamped migrations files in the *Migrations* folder. To do that you'll find and open only the files that need to be changed, then perform a global change on the opened files. The only file in the *Migrations* folder you should change is *Migrations\Configuration.cs.*

1. **IMPORTANT**

   Begin by closing all the open files in Visual Studio.

2. Click **Find and Replace -- Find all Files** in the **Edit** menu, and then search for all files in the project that contain `InstructorID`.

3. Open each file in the **Find Results** window ***except*** the <time-stamp>*_.cs* migration files in the *Migrations* folder, by double-clicking one line for each file.

4. Open the **Replace in Files** dialog and change **Look in** to **All Open Documents**.

5. Use the **Replace in Files** dialog to change all `InstructorID` to `PersonID.`

6. Find all the files in the project that contain `StudentID`.

7. Open each file in the **Find Results** window ***except*** the <time-stamp>_*.cs* migration files in the *Migrations* folder, by double-clicking one line for each file.

8. Open the **Replace in Files** dialog and change **Look in** to **All Open Documents**.

9. Use the **Replace in Files** dialog to change all `StudentID` to `PersonID`.

10. Build the project.

(Note that this demonstrates a *disadvantage* of the `classnameID` pattern for naming primary keys. If you had named primary keys ID without prefixing the class name, *no* renaming would be necessary now.)

Create and Update a Migrations File

In the Package Manager Console (PMC), enter the following command:

```
Add-Migration Inheritance
```

Run the `Update-Database` command in the PMC. The command will fail at this point because we have existing data that migrations doesn't know how to handle. You get the following error:

The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Department_dbo.Person_PersonID". The conflict occurred in database "ContosoUniversity", table "dbo.Person", column 'PersonID'.

Open *Migrations<timestamp>_Inheritance.cs* and replace the `Up` method with the following code:

```
public override void Up()
{
    DropForeignKey("dbo.Department", "InstructorID", "dbo.Instructor");
    DropForeignKey("dbo.OfficeAssignment", "InstructorID", "dbo.Instructor");
    DropForeignKey("dbo.Enrollment", "StudentID", "dbo.Student");
    DropForeignKey("dbo.CourseInstructor", "InstructorID", "dbo.Instructor");
    DropIndex("dbo.Department", new[] { "InstructorID" });
    DropIndex("dbo.OfficeAssignment", new[] { "InstructorID" });
    DropIndex("dbo.Enrollment", new[] { "StudentID" });
    DropIndex("dbo.CourseInstructor", new[] { "InstructorID" });
    RenameColumn(table: "dbo.Department", name: "InstructorID", newName: "PersonID");
    RenameColumn(table: "dbo.OfficeAssignment", name: "InstructorID", newName: "PersonID");
    RenameColumn(table: "dbo.Enrollment", name: "StudentID", newName: "PersonID");
    RenameColumn(table: "dbo.CourseInstructor", name: "InstructorID", newName: "PersonID");
    CreateTable(
        "dbo.Person",
        c => new
            {
                PersonID = c.Int(nullable: false, identity: true),
                LastName = c.String(maxLength: 50),
                FirstName = c.String(maxLength: 50),
                HireDate = c.DateTime(),
                EnrollmentDate = c.DateTime(),
                Discriminator = c.String(nullable: false, maxLength: 128),
                OldId = c.Int(nullable: false)
            })
        .PrimaryKey(t => t.PersonID);

    // Copy existing Student and Instructor data into new Person table.
    Sql("INSERT INTO dbo.Person (LastName, FirstName, HireDate, EnrollmentDate, Discriminator, OldId) SELECT
LastName, FirstName, null AS HireDate, EnrollmentDate, 'Student' AS Discriminator, StudentId AS OldId FROM
dbo.Student");
    Sql("INSERT INTO dbo.Person (LastName, FirstName, HireDate, EnrollmentDate, Discriminator, OldId) SELECT
LastName, FirstName, HireDate, null AS EnrollmentDate, 'Instructor' AS Discriminator, InstructorId AS OldId
FROM dbo.Instructor");

    // Fix up existing relationships to match new PK's.
    Sql("UPDATE dbo.Enrollment SET PersonId = (SELECT PersonId FROM dbo.Person WHERE OldId =
Enrollment.PersonId AND Discriminator = 'Student')");
    Sql("UPDATE dbo.Department SET PersonId = (SELECT PersonId FROM dbo.Person WHERE OldId =
Department.PersonId AND Discriminator = 'Instructor')");
    Sql("UPDATE dbo.OfficeAssignment SET PersonId = (SELECT PersonId FROM dbo.Person WHERE OldId =
OfficeAssignment.PersonId AND Discriminator = 'Instructor')");
    Sql("UPDATE dbo.CourseInstructor SET PersonId = (SELECT PersonId FROM dbo.Person WHERE OldId =
CourseInstructor.PersonId AND Discriminator = 'Instructor')");

    // Remove temporary key
    DropColumn("dbo.Person", "OldId");

    AddForeignKey("dbo.Department", "PersonID", "dbo.Person", "PersonID");
    AddForeignKey("dbo.OfficeAssignment", "PersonID", "dbo.Person", "PersonID");
    AddForeignKey("dbo.Enrollment", "PersonID", "dbo.Person", "PersonID", cascadeDelete: true);
    AddForeignKey("dbo.CourseInstructor", "PersonID", "dbo.Person", "PersonID", cascadeDelete: true);
    CreateIndex("dbo.Department", "PersonID");
    CreateIndex("dbo.OfficeAssignment", "PersonID");
    CreateIndex("dbo.Enrollment", "PersonID");
    CreateIndex("dbo.CourseInstructor", "PersonID");
    DropTable("dbo.Instructor");
    DropTable("dbo.Student");
}
```

Run the `update-database` command again.

NOTE

It's possible to get other errors when migrating data and making schema changes. If you get migration errors you can't resolve, you can continue with the tutorial by changing the connection string in the *Web.config* file or deleting the database. The simplest approach is to rename the database in the *Web.config* file. For example, change the database name to CU_test as shown in the following example:

```
<add name="SchoolContext" connectionString="Data Source=(LocalDb)\v11.0;Initial Catalog=CU_Test;
      Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\CU_Test.mdf"
      providerName="System.Data.SqlClient" />
```

With a new database, there is no data to migrate, and the `update-database` command is much more likely to complete without errors. For instructions on how to delete the database, see How to Drop a Database from Visual Studio 2012. If you take this approach in order to continue with the tutorial, skip the deployment step at the end of this tutorial, since the deployed site would get the same error when it runs migrations automatically. If you want to troubleshoot a migrations error, the best resource is one of the Entity Framework forums or StackOverflow.com.

Testing

Run the site and try various pages. Everything works the same as it did before.

In **Server Explorer,** expand **SchoolContext** and then **Tables**, and you see that the **Student** and **Instructor** tables have been replaced by a **Person** table. Expand the **Person** table and you see that it has all of the columns that used to be in the **Student** and **Instructor** tables.

Right-click the Person table, and then click **Show Table Data** to see the discriminator column.

dbo.Person [Data]

Max Rows: 1000

	PersonID	LastName	FirstName	HireDate	EnrollmentDate	Discriminator
▶	1	Alexander	Carson	NULL	9/1/2010 12:00...	Student
	2	Alonso	Meredith	NULL	9/1/2012 12:00...	Student
	3	Anand	Arturo	NULL	9/1/2013 12:00...	Student
	4	Barzdukas	Gytis	NULL	9/1/2012 12:00...	Student
	5	Li	Yan	NULL	9/1/2012 12:00...	Student
	6	Justice	Peggy	NULL	9/1/2011 12:00...	Student
	7	Norman	Laura	NULL	9/1/2013 12:00...	Student

*	NULL	NULL	NULL	NULL	NULL	NULL

The following diagram illustrates the structure of the new School database:

Summary

Table-per-hierarchy inheritance has now been implemented for the `Person`, `Student`, and `Instructor` classes. For more information about this and other inheritance structures, see Inheritance Mapping Strategies on Morteza Manavi's blog. In the next tutorial you'll see some ways to implement the repository and unit of work patterns.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Implementing the Repository and Unit of Work Patterns in an ASP.NET MVC Application (9 of 10)

2/20/2020 • 20 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you used inheritance to reduce redundant code in the `Student` and `Instructor` entity classes. In this tutorial you'll see some ways to use the repository and unit of work patterns for CRUD operations. As in the previous tutorial, in this one you'll change the way your code works with pages you already created rather than creating new pages.

The Repository and Unit of Work Patterns

The repository and unit of work patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD).

In this tutorial you'll implement a repository class for each entity type. For the `Student` entity type you'll create a repository interface and a repository class. When you instantiate the repository in your controller, you'll use the interface so that the controller will accept a reference to any object that implements the repository interface. When the controller runs under a web server, it receives a repository that works with the Entity Framework. When the controller runs under a unit test class, it receives a repository that works with data stored in a way that you can easily manipulate for testing, such as an in-memory collection.

Later in the tutorial you'll use multiple repositories and a unit of work class for the `Course` and `Department` entity types in the `Course` controller. The unit of work class coordinates the work of multiple repositories by creating a single database context class shared by all of them. If you wanted to be able to perform automated unit testing, you'd create and use interfaces for these classes in the same way you did for the `Student` repository. However, to keep the tutorial simple, you'll create and use these classes without interfaces.

The following illustration shows one way to conceptualize the relationships between the controller and context classes compared to not using the repository or unit of work pattern at all.

You won't create unit tests in this tutorial series. For an introduction to TDD with an MVC application that uses the repository pattern, see Walkthrough: Using TDD with ASP.NET MVC. For more information about the repository pattern, see the following resources:

- The Repository Pattern on MSDN.
- Using Repository and Unit of Work patterns with Entity Framework 4.0 on the Entity Framework team blog.
- Agile Entity Framework 4 Repository series of posts on Julie Lerman's blog.
- Building the Account at a Glance HTML5/jQuery Application on Dan Wahlin's blog.

> **NOTE**
> There are many ways to implement the repository and unit of work patterns. You can use repository classes with or without a unit of work class. You can implement a single repository for all entity types, or one for each type. If you implement one for each type, you can use separate classes, a generic base class and derived classes, or an abstract base class and derived classes. You can include business logic in your repository or restrict it to data access logic. You can also build an abstraction layer into your database context class by using IDbSet interfaces there instead of DbSet types for your entity sets. The approach to implementing an abstraction layer shown in this tutorial is one option for you to consider, not a recommendation for all scenarios and environments.

Creating the Student Repository Class

In the *DAL* folder, create a class file named *IStudentRepository.cs* and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using ContosoUniversity.Models;

namespace ContosoUniversity.DAL
{
    public interface IStudentRepository : IDisposable
    {
        IEnumerable<Student> GetStudents();
        Student GetStudentByID(int studentId);
        void InsertStudent(Student student);
        void DeleteStudent(int studentID);
        void UpdateStudent(Student student);
        void Save();
    }
}
```

This code declares a typical set of CRUD methods, including two read methods — one that returns all `Student` entities, and one that finds a single `Student` entity by ID.

In the *DAL* folder, create a class file named *StudentRepository.cs* file. Replace the existing code with the following code, which implements the `IStudentRepository` interface:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Data;
using ContosoUniversity.Models;

namespace ContosoUniversity.DAL
{
    public class StudentRepository : IStudentRepository, IDisposable
    {
        private SchoolContext context;

        public StudentRepository(SchoolContext context)
        {
            this.context = context;
        }

        public IEnumerable<Student> GetStudents()
        {
            return context.Students.ToList();
        }

        public Student GetStudentByID(int id)
        {
            return context.Students.Find(id);
        }

        public void InsertStudent(Student student)
        {
            context.Students.Add(student);
        }

        public void DeleteStudent(int studentID)
        {
            Student student = context.Students.Find(studentID);
            context.Students.Remove(student);
        }

        public void UpdateStudent(Student student)
        {
            context.Entry(student).State = EntityState.Modified;
        }
```

```
        public void Save()
        {
            context.SaveChanges();
        }

        private bool disposed = false;

        protected virtual void Dispose(bool disposing)
        {
            if (!this.disposed)
            {
                if (disposing)
                {
                    context.Dispose();
                }
            }
            this.disposed = true;
        }

        public void Dispose()
        {
            Dispose(true);
            GC.SuppressFinalize(this);
        }
    }
}
```

The database context is defined in a class variable, and the constructor expects the calling object to pass in an instance of the context:

```
private SchoolContext context;

public StudentRepository(SchoolContext context)
{
    this.context = context;
}
```

You could instantiate a new context in the repository, but then if you used multiple repositories in one controller, each would end up with a separate context. Later you'll use multiple repositories in the `Course` controller, and you'll see how a unit of work class can ensure that all repositories use the same context.

The repository implements IDisposable and disposes the database context as you saw earlier in the controller, and its CRUD methods make calls to the database context in the same way that you saw earlier.

Change the Student Controller to Use the Repository

In *StudentController.cs*, replace the code currently in the class with the following code. The changes are highlighted.

```
using System;
using System.Data;
using System.Linq;
using System.Web.Mvc;
using ContosoUniversity.Models;
using ContosoUniversity.DAL;
using PagedList;

namespace ContosoUniversity.Controllers
{
   public class StudentController : Controller
   {
      private IStudentRepository studentRepository;
```

```
    public StudentController()
    {
       this.studentRepository = new StudentRepository(new SchoolContext());
    }

    public StudentController(IStudentRepository studentRepository)
    {
       this.studentRepository = studentRepository;
    }

    //
    // GET: /Student/

    public ViewResult Index(string sortOrder, string currentFilter, string searchString, int? page)
    {
       ViewBag.CurrentSort = sortOrder;
       ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
       ViewBag.DateSortParm = sortOrder == "Date" ? "date_desc" : "Date";

       if (searchString != null)
       {
          page = 1;
       }
       else
       {
          searchString = currentFilter;
       }
       ViewBag.CurrentFilter = searchString;

       var students = from s in studentRepository.GetStudents()
                      select s;
       if (!String.IsNullOrEmpty(searchString))
       {
          students = students.Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
                                  || s.FirstMidName.ToUpper().Contains(searchString.ToUpper()));
       }
       switch (sortOrder)
       {
          case "name_desc":
             students = students.OrderByDescending(s => s.LastName);
             break;
          case "Date":
             students = students.OrderBy(s => s.EnrollmentDate);
             break;
          case "date_desc":
             students = students.OrderByDescending(s => s.EnrollmentDate);
             break;
          default:  // Name ascending
             students = students.OrderBy(s => s.LastName);
             break;
       }

       int pageSize = 3;
       int pageNumber = (page ?? 1);
       return View(students.ToPagedList(pageNumber, pageSize));
    }

    //
    // GET: /Student/Details/5

    public ViewResult Details(int id)
    {
       Student student = studentRepository.GetStudentByID(id);
       return View(student);
    }

    //
    // GET: /Student/Create
```

```
      // GET: /Student/Create

      public ActionResult Create()
      {
         return View();
      }

      //
      // POST: /Student/Create

      [HttpPost]
      [ValidateAntiForgeryToken]
      public ActionResult Create(
         [Bind(Include = "LastName, FirstMidName, EnrollmentDate")]
           Student student)
      {
         try
         {
            if (ModelState.IsValid)
            {
               studentRepository.InsertStudent(student);
               studentRepository.Save();
               return RedirectToAction("Index");
            }
         }
         catch (DataException /* dex */)
         {
            //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.
            ModelState.AddModelError(string.Empty, "Unable to save changes. Try again, and if the problem
persists contact your system administrator.");
         }
         return View(student);
      }

      //
      // GET: /Student/Edit/5

      public ActionResult Edit(int id)
      {
         Student student = studentRepository.GetStudentByID(id);
         return View(student);
      }

      //
      // POST: /Student/Edit/5

      [HttpPost]
      [ValidateAntiForgeryToken]
      public ActionResult Edit(
         [Bind(Include = "LastName, FirstMidName, EnrollmentDate")]
         Student student)
      {
         try
         {
            if (ModelState.IsValid)
            {
               studentRepository.UpdateStudent(student);
               studentRepository.Save();
               return RedirectToAction("Index");
            }
         }
         catch (DataException /* dex */)
         {
            //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.
            ModelState.AddModelError(string.Empty, "Unable to save changes. Try again, and if the problem
persists contact your system administrator.");
         }
         return View(student);
```

```
            return View(student);
        }

        //
        // GET: /Student/Delete/5

        public ActionResult Delete(bool? saveChangesError = false, int id = 0)
        {
            if (saveChangesError.GetValueOrDefault())
            {
                ViewBag.ErrorMessage = "Delete failed. Try again, and if the problem persists see your system
administrator.";
            }
            Student student = studentRepository.GetStudentByID(id);
            return View(student);
        }

        //
        // POST: /Student/Delete/5

        [HttpPost]
        [ValidateAntiForgeryToken]
        public ActionResult Delete(int id)
        {
            try
            {
                Student student = studentRepository.GetStudentByID(id);
                studentRepository.DeleteStudent(id);
                studentRepository.Save();
            }
            catch (DataException /* dex */)
            {
                //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.
                return RedirectToAction("Delete", new { id = id, saveChangesError = true });
            }
            return RedirectToAction("Index");
        }

        protected override void Dispose(bool disposing)
        {
            studentRepository.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

The controller now declares a class variable for an object that implements the `IStudentRepository` interface instead of the context class:

```
private IStudentRepository studentRepository;
```

The default (parameterless) constructor creates a new context instance, and an optional constructor allows the caller to pass in a context instance.

```
public StudentController()
{
    this.studentRepository = new StudentRepository(new SchoolContext());
}

public StudentController(IStudentRepository studentRepository)
{
    this.studentRepository = studentRepository;
}
```

(If you were using *dependency injection*, or DI, you wouldn't need the default constructor because the DI software would ensure that the correct repository object would always be provided.)

In the CRUD methods, the repository is now called instead of the context:

```
var students = from s in studentRepository.GetStudents()
               select s;
```

```
Student student = studentRepository.GetStudentByID(id);
```

```
studentRepository.InsertStudent(student);
studentRepository.Save();
```

```
studentRepository.UpdateStudent(student);
studentRepository.Save();
```

```
studentRepository.DeleteStudent(id);
studentRepository.Save();
```

And the `Dispose` method now disposes the repository instead of the context:

```
studentRepository.Dispose();
```

Run the site and click the **Students** tab.

The page looks and works the same as it did before you changed the code to use the repository, and the other Student pages also work the same. However, there's an important difference in the way the `Index` method of the controller does filtering and ordering. The original version of this method contained the following code:

```
var students = from s in context.Students
               select s;
if (!String.IsNullOrEmpty(searchString))
{
    students = students.Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
                           || s.FirstMidName.ToUpper().Contains(searchString.ToUpper()));
}
```

The updated `Index` method contains the following code:

```
var students = from s in studentRepository.GetStudents()
                select s;
if (!String.IsNullOrEmpty(searchString))
{
    students = students.Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())
                        || s.FirstMidName.ToUpper().Contains(searchString.ToUpper()));
}
```

Only the highlighted code has changed.

In the original version of the code, `students` is typed as an `IQueryable` object. The query isn't sent to the database until it's converted into a collection using a method such as `ToList`, which doesn't occur until the Index view accesses the student model. The `Where` method in the original code above becomes a `WHERE` clause in the SQL query that is sent to the database. That in turn means that only the selected entities are returned by the database. However, as a result of changing `context.Students` to `studentRepository.GetStudents()`, the `students` variable after this statement is an `IEnumerable` collection that includes all students in the database. The end result of applying the `Where` method is the same, but now the work is done in memory on the web server and not by the database. For queries that return large volumes of data, this can be inefficient.

TIP

IQueryable vs. IEnumerable

After you implement the repository as shown here, even if you enter something in the **Search** box the query sent to SQL Server returns all Student rows because it doesn't include your search criteria:

```
public ViewResult Index(string sortOrder, string currentFilter, string
{
    ViewBag.CurrentSort = sortOrder;
    ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "Name des
    ViewBag.DateSortParm = sortOrder == "Date" ? "Date desc" : "Date";

    if (searchString != null)
        page = 1;
    else
        searchString = currentFilter;

    ViewBag.CurrentFilter = searchString;

    var students = from s in studentRepository.GetStudents()
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.ToUpper().Contains(sear
                                || s.FirstMidName.ToUpper().Contains(searc
    }
            switch (sortOrder)
            {
                case "Name desc":
                    students = students.OrderByDescending(s => s.LastN
                    break;
                case "Date":
```

```
SELECT
'0X0X' AS [C1],
[Extent1].[PersonID] AS [PersonID],
[Extent1].[LastName] AS [LastName],
[Extent1].[FirstName] AS [FirstName],
[Extent1].[EnrollmentDate] AS [EnrollmentDate]
FROM [dbo].[Person] AS [Extent1]
WHERE [Extent1].[Discriminator] = N'Student'
```

This query returns all of the student data because the repository executed the query without knowing about the search criteria. The process of sorting, applying search criteria, and selecting a subset of the data for paging (showing only 3 rows in this case) is done in memory later when the `ToPagedList` method is called on the `IEnumerable` collection.

In the previous version of the code (before you implemented the repository), the query is not sent to the database until after you apply the search criteria, when `ToPagedList` is called on the `IQueryable` object.

StudentController.cs

ContosoUniversity.Controllers.StudentController

```
public ViewResult Index(string sortOrder, string currentFilter, string sea
{
    ViewBag.CurrentSort = sortOrder;
    ViewBag.NameSortParm = String.IsNullOrEmpty(sortOrder) ? "Name desc" :
    ViewBag.DateSortParm = sortOrder == "Date" ? "Date desc" : "Date";

    if (searchString != null)
        page = 1;
    else
        searchString = currentFilter;

    ViewBag.CurrentFilter = searchString;

    var students = from s in db.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.ToUpper().Contains(searc
                                   || s.FirstMidName.ToUpper().Contains(search
    }
    switch (sortOrder)
    {
        case "Name desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "Date desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:  // Name ascending
            students = students.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    int pageNumber = (page ?? 1);
    return View(students.ToPagedList(pageNumber, pageSize));
}
```

When ToPagedList is called on an `IQueryable` object, the query sent to SQL Server specifies the search string, and as a result only rows that meet the search criteria are returned, and no filtering needs to be done in memory.

```
exec sp_executesql N'SELECT TOP (3)
[Project1].[StudentID] AS [StudentID],
[Project1].[LastName] AS [LastName],
[Project1].[FirstName] AS [FirstName],
[Project1].[EnrollmentDate] AS [EnrollmentDate]
FROM ( SELECT [Project1].[StudentID] AS [StudentID], [Project1].[LastName] AS [LastName], [Project1].
[FirstName] AS [FirstName], [Project1].[EnrollmentDate] AS [EnrollmentDate], row_number() OVER (ORDER BY
[Project1].[LastName] ASC) AS [row_number]
FROM ( SELECT
    [Extent1].[StudentID] AS [StudentID],
    [Extent1].[LastName] AS [LastName],
    [Extent1].[FirstName] AS [FirstName],
    [Extent1].[EnrollmentDate] AS [EnrollmentDate]
    FROM [dbo].[Student] AS [Extent1]
    WHERE (( CAST(CHARINDEX(UPPER(@p__linq__0), UPPER([Extent1].[LastName])) AS int)) > 0) OR ((
CAST(CHARINDEX(UPPER(@p__linq__1), UPPER([Extent1].[FirstName])) AS int)) > 0)
)  AS [Project1]
)  AS [Project1]
WHERE [Project1].[row_number] > 0
ORDER BY [Project1].[LastName] ASC',N'@p__linq__0 nvarchar(4000),@p__linq__1
nvarchar(4000)',@p__linq__0=N'Alex',@p__linq__1=N'Alex'
```

(The following tutorial explains how to examine queries sent to SQL Server.)

The following section shows how to implement repository methods that enable you to specify that this work should be done by the database.

You've now created an abstraction layer between the controller and the Entity Framework database context. If you were going to perform automated unit testing with this application, you could create an alternative repository class in a unit test project that implements `IStudentRepository`. Instead of calling the context to read and write data, this mock repository class could manipulate in-memory collections in order to test controller functions.

Implement a Generic Repository and a Unit of Work Class

Creating a repository class for each entity type could result in a lot of redundant code, and it could result in partial updates. For example, suppose you have to update two different entity types as part of the same transaction. If each uses a separate database context instance, one might succeed and the other might fail. One way to minimize redundant code is to use a generic repository, and one way to ensure that all repositories use the same database context (and thus coordinate all updates) is to use a unit of work class.

In this section of the tutorial, you'll create a `GenericRepository` class and a `UnitOfWork` class, and use them in the `Course` controller to access both the `Department` and the `Course` entity sets. As explained earlier, to keep this part of the tutorial simple, you aren't creating interfaces for these classes. But if you were going to use them to facilitate TDD, you'd typically implement them with interfaces the same way you did the `Student` repository.

Create a Generic Repository

In the *DAL* folder, create *GenericRepository.cs* and replace the existing code with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Data;
using System.Data.Entity;
using ContosoUniversity.Models;
using System.Linq.Expressions;

namespace ContosoUniversity.DAL
{
    public class GenericRepository<TEntity> where TEntity : class
    {
        internal SchoolContext context;
        internal DbSet<TEntity> dbSet;
```

```
        internal DbSet<TEntity> dbSet;

        public GenericRepository(SchoolContext context)
        {
            this.context = context;
            this.dbSet = context.Set<TEntity>();
        }

        public virtual IEnumerable<TEntity> Get(
            Expression<Func<TEntity, bool>> filter = null,
            Func<IQueryable<TEntity>, IOrderedQueryable<TEntity>> orderBy = null,
            string includeProperties = "")
        {
            IQueryable<TEntity> query = dbSet;

            if (filter != null)
            {
                query = query.Where(filter);
            }

            foreach (var includeProperty in includeProperties.Split
                (new char[] { ',' }, StringSplitOptions.RemoveEmptyEntries))
            {
                query = query.Include(includeProperty);
            }

            if (orderBy != null)
            {
                return orderBy(query).ToList();
            }
            else
            {
                return query.ToList();
            }
        }

        public virtual TEntity GetByID(object id)
        {
            return dbSet.Find(id);
        }

        public virtual void Insert(TEntity entity)
        {
            dbSet.Add(entity);
        }

        public virtual void Delete(object id)
        {
            TEntity entityToDelete = dbSet.Find(id);
            Delete(entityToDelete);
        }

        public virtual void Delete(TEntity entityToDelete)
        {
            if (context.Entry(entityToDelete).State == EntityState.Detached)
            {
                dbSet.Attach(entityToDelete);
            }
            dbSet.Remove(entityToDelete);
        }

        public virtual void Update(TEntity entityToUpdate)
        {
            dbSet.Attach(entityToUpdate);
            context.Entry(entityToUpdate).State = EntityState.Modified;
        }
    }
}
```

Class variables are declared for the database context and for the entity set that the repository is instantiated for:

```
internal SchoolContext context;
internal DbSet dbSet;
```

The constructor accepts a database context instance and initializes the entity set variable:

```
public GenericRepository(SchoolContext context)
{
    this.context = context;
    this.dbSet = context.Set<TEntity>();
}
```

The `Get` method uses lambda expressions to allow the calling code to specify a filter condition and a column to order the results by, and a string parameter lets the caller provide a comma-delimited list of navigation properties for eager loading:

```
public virtual IEnumerable<TEntity> Get(
    Expression<Func<TEntity, bool>> filter = null,
    Func<IQueryable<TEntity>, IOrderedQueryable<TEntity>> orderBy = null,
    string includeProperties = "")
```

The code `Expression<Func<TEntity, bool>> filter` means the caller will provide a lambda expression based on the `TEntity` type, and this expression will return a Boolean value. For example, if the repository is instantiated for the `Student` entity type, the code in the calling method might specify `student => student.LastName == "Smith` " for the `filter` parameter.

The code `Func<IQueryable<TEntity>, IOrderedQueryable<TEntity>> orderBy` also means the caller will provide a lambda expression. But in this case, the input to the expression is an `IQueryable` object for the `TEntity` type. The expression will return an ordered version of that `IQueryable` object. For example, if the repository is instantiated for the `Student` entity type, the code in the calling method might specify `q => q.OrderBy(s => s.LastName)` for the `orderBy` parameter.

The code in the `Get` method creates an `IQueryable` object and then applies the filter expression if there is one:

```
IQueryable<TEntity> query = dbSet;

if (filter != null)
{
    query = query.Where(filter);
}
```

Next it applies the eager-loading expressions after parsing the comma-delimited list:

```
foreach (var includeProperty in includeProperties.Split
    (new char[] { ',' }, StringSplitOptions.RemoveEmptyEntries))
{
    query = query.Include(includeProperty);
}
```

Finally, it applies the `orderBy` expression if there is one and returns the results; otherwise it returns the results from the unordered query:

```
if (orderBy != null)
{
    return orderBy(query).ToList();
}
else
{
    return query.ToList();
}
```

When you call the `Get` method, you could do filtering and sorting on the `IEnumerable` collection returned by the method instead of providing parameters for these functions. But the sorting and filtering work would then be done in memory on the web server. By using these parameters, you ensure that the work is done by the database rather than the web server. An alternative is to create derived classes for specific entity types and add specialized `Get` methods, such as `GetStudentsInNameOrder` or `GetStudentsByName`. However, in a complex application, this can result in a large number of such derived classes and specialized methods, which could be more work to maintain.

The code in the `GetByID`, `Insert`, and `Update` methods is similar to what you saw in the non-generic repository. (You aren't providing an eager loading parameter in the `GetByID` signature, because you can't do eager loading with the `Find` method.)

Two overloads are provided for the `Delete` method:

```
public virtual void Delete(object id)
{
    TEntity entityToDelete = dbSet.Find(id);
    dbSet.Remove(entityToDelete);
}

public virtual void Delete(TEntity entityToDelete)
{
    if (context.Entry(entityToDelete).State == EntityState.Detached)
    {
        dbSet.Attach(entityToDelete);
    }
    dbSet.Remove(entityToDelete);
}
```

One of these lets you pass in just the ID of the entity to be deleted, and one takes an entity instance. As you saw in the Handling Concurrency tutorial, for concurrency handling you need a `Delete` method that takes an entity instance that includes the original value of a tracking property.

This generic repository will handle typical CRUD requirements. When a particular entity type has special requirements, such as more complex filtering or ordering, you can create a derived class that has additional methods for that type.

Creating the Unit of Work Class

The unit of work class serves one purpose: to make sure that when you use multiple repositories, they share a single database context. That way, when a unit of work is complete you can call the `SaveChanges` method on that instance of the context and be assured that all related changes will be coordinated. All that the class needs is a `Save` method and a property for each repository. Each repository property returns a repository instance that has been instantiated using the same database context instance as the other repository instances.

In the *DAL* folder, create a class file named *UnitOfWork.cs* and replace the template code with the following code:

```
using System;
using ContosoUniversity.Models;

namespace ContosoUniversity.DAL
{
    public class UnitOfWork : IDisposable
    {
        private SchoolContext context = new SchoolContext();
        private GenericRepository<Department> departmentRepository;
        private GenericRepository<Course> courseRepository;

        public GenericRepository<Department> DepartmentRepository
        {
            get
            {

                if (this.departmentRepository == null)
                {
                    this.departmentRepository = new GenericRepository<Department>(context);
                }
                return departmentRepository;
            }
        }

        public GenericRepository<Course> CourseRepository
        {
            get
            {

                if (this.courseRepository == null)
                {
                    this.courseRepository = new GenericRepository<Course>(context);
                }
                return courseRepository;
            }
        }

        public void Save()
        {
            context.SaveChanges();
        }

        private bool disposed = false;

        protected virtual void Dispose(bool disposing)
        {
            if (!this.disposed)
            {
                if (disposing)
                {
                    context.Dispose();
                }
            }
            this.disposed = true;
        }

        public void Dispose()
        {
            Dispose(true);
            GC.SuppressFinalize(this);
        }
    }
}
```

The code creates class variables for the database context and each repository. For the `context` variable, a new context is instantiated:

```
private SchoolContext context = new SchoolContext();
private GenericRepository<Department> departmentRepository;
private GenericRepository<Course> courseRepository;
```

Each repository property checks whether the repository already exists. If not, it instantiates the repository, passing in the context instance. As a result, all repositories share the same context instance.

```
public GenericRepository<Department> DepartmentRepository
{
    get
    {

        if (this.departmentRepository == null)
        {
            this.departmentRepository = new GenericRepository<Department>(context);
        }
        return departmentRepository;
    }
}
```

The `Save` method calls `SaveChanges` on the database context.

Like any class that instantiates a database context in a class variable, the `UnitOfWork` class implements `IDisposable` and disposes the context.

Changing the Course Controller to use the UnitOfWork Class and Repositories

Replace the code you currently have in *CourseController.cs* with the following code:

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Data.Entity;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using ContosoUniversity.Models;
using ContosoUniversity.DAL;

namespace ContosoUniversity.Controllers
{
   public class CourseController : Controller
   {
      private UnitOfWork unitOfWork = new UnitOfWork();

      //
      // GET: /Course/

      public ViewResult Index()
      {
         var courses = unitOfWork.CourseRepository.Get(includeProperties: "Department");
         return View(courses.ToList());
      }

      //
      // GET: /Course/Details/5

      public ViewResult Details(int id)
      {
         Course course = unitOfWork.CourseRepository.GetByID(id);
         return View(course);
      }

      //
```

```
      // GET: /Course/Create

      public ActionResult Create()
      {
         PopulateDepartmentsDropDownList();
         return View();
      }

      [HttpPost]
      [ValidateAntiForgeryToken]
      public ActionResult Create(
          [Bind(Include = "CourseID,Title,Credits,DepartmentID")]
         Course course)
      {
         try
         {
            if (ModelState.IsValid)
            {
               unitOfWork.CourseRepository.Insert(course);
               unitOfWork.Save();
               return RedirectToAction("Index");
            }
         }
         catch (DataException /* dex */)
         {
            //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.)
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
         }
         PopulateDepartmentsDropDownList(course.DepartmentID);
         return View(course);
      }

      public ActionResult Edit(int id)
      {
         Course course = unitOfWork.CourseRepository.GetByID(id);
         PopulateDepartmentsDropDownList(course.DepartmentID);
         return View(course);
      }

      [HttpPost]
      [ValidateAntiForgeryToken]
      public ActionResult Edit(
           [Bind(Include = "CourseID,Title,Credits,DepartmentID")]
         Course course)
      {
         try
         {
            if (ModelState.IsValid)
            {
               unitOfWork.CourseRepository.Update(course);
               unitOfWork.Save();
               return RedirectToAction("Index");
            }
         }
         catch (DataException /* dex */)
         {
            //Log the error (uncomment dex variable name after DataException and add a line here to write a
log.)
            ModelState.AddModelError("", "Unable to save changes. Try again, and if the problem persists, see
your system administrator.");
         }
         PopulateDepartmentsDropDownList(course.DepartmentID);
         return View(course);
      }

      private void PopulateDepartmentsDropDownList(object selectedDepartment = null)
      {
```

```
        {
           var departmentsQuery = unitOfWork.DepartmentRepository.Get(
               orderBy: q => q.OrderBy(d => d.Name));
           ViewBag.DepartmentID = new SelectList(departmentsQuery, "DepartmentID", "Name", selectedDepartment);
        }

        //
        // GET: /Course/Delete/5

        public ActionResult Delete(int id)
        {
           Course course = unitOfWork.CourseRepository.GetByID(id);
           return View(course);
        }

        //
        // POST: /Course/Delete/5

        [HttpPost, ActionName("Delete")]
        [ValidateAntiForgeryToken]
        public ActionResult DeleteConfirmed(int id)
        {
           Course course = unitOfWork.CourseRepository.GetByID(id);
           unitOfWork.CourseRepository.Delete(id);
           unitOfWork.Save();
           return RedirectToAction("Index");
        }

        protected override void Dispose(bool disposing)
        {
           unitOfWork.Dispose();
           base.Dispose(disposing);
        }
     }
  }
```

This code adds a class variable for the `UnitOfWork` class. (If you were using interfaces here, you wouldn't initialize the variable here; instead, you'd implement a pattern of two constructors just as you did for the `Student` repository.)

```
private UnitOfWork unitOfWork = new UnitOfWork();
```

In the rest of the class, all references to the database context are replaced by references to the appropriate repository, using `UnitOfWork` properties to access the repository. The `Dispose` method disposes the `UnitOfWork` instance.

```
var courses = unitOfWork.CourseRepository.Get(includeProperties: "Department");
// ...
Course course = unitOfWork.CourseRepository.GetByID(id);
// ...
unitOfWork.CourseRepository.Insert(course);
unitOfWork.Save();
// ...
Course course = unitOfWork.CourseRepository.GetByID(id);
// ...
unitOfWork.CourseRepository.Update(course);
unitOfWork.Save();
// ...
var departmentsQuery = unitOfWork.DepartmentRepository.Get(
    orderBy: q => q.OrderBy(d => d.Name));
// ...
Course course = unitOfWork.CourseRepository.GetByID(id);
// ...
unitOfWork.CourseRepository.Delete(id);
unitOfWork.Save();
// ...
unitOfWork.Dispose();
```

Run the site and click the **Courses** tab.

The page looks and works the same as it did before your changes, and the other Course pages also work the same.

Summary

You have now implemented both the repository and unit of work patterns. You have used lambda expressions as method parameters in the generic repository. For more information about how to use these expressions with an `IQueryable` object, see IQueryable(T) Interface (System.Linq) in the MSDN Library. In the next tutorial you'll learn how to handle some advanced scenarios.

Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

Advanced Entity Framework Scenarios for an MVC Web Application (10 of 10)

9/16/2020 • 18 minutes to read • Edit Online

by Tom Dykstra

Download Completed Project

The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series. You can start the tutorial series from the beginning or download a starter project for this chapter and start here.

> **NOTE**
>
> If you run into a problem you can't resolve, download the completed chapter and try to reproduce your problem. You can generally find the solution to the problem by comparing your code to the completed code. For some common errors and how to solve them, see Errors and Workarounds.

In the previous tutorial you implemented the repository and unit of work patterns. This tutorial covers the following topics:

- Performing raw SQL queries.
- Performing no-tracking queries.
- Examining queries sent to the database.
- Working with proxy classes.
- Disabling automatic detection of changes.
- Disabling validation when saving changes.
- Errors and Work Arounds

For most of these topics, you'll work with pages that you already created. To use raw SQL to do bulk updates you'll create a new page that updates the number of credits of all courses in the database:

And to use a no-tracking query you'll add new validation logic to the Department Edit page:

Performing Raw SQL Queries

The Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options:

- Use the `DbSet.SqlQuery` method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they are automatically tracked by the database context unless you turn tracking off. (See the following section about the `AsNoTracking` method.)
- Use the `Database.SqlQuery` method for queries that return types that aren't entities. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.
- Use the Database.ExecuteSqlCommand for non-query commands.

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created, and these methods make it possible for you to handle such exceptions.

As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Calling a Query that Returns Entities

Suppose you want the `GenericRepository` class to provide additional filtering and sorting flexibility without requiring that you create a derived class with additional methods. One way to achieve that would be to add a method that accepts a SQL query. You could then specify any kind of filtering or sorting you want in the controller, such as a `Where` clause that depends on a joins or a subquery. In this section you'll see how to implement such a method.

Create the `GetWithRawSql` method by adding the following code to *GenericRepository.cs*:

```
public virtual IEnumerable<TEntity> GetWithRawSql(string query, params object[] parameters)
{
    return dbSet.SqlQuery(query, parameters).ToList();
}
```

In *CourseController.cs*, call the new method from the `Details` method, as shown in the following example:

```
public ActionResult Details(int id)
{
    var query = "SELECT * FROM Course WHERE CourseID = @p0";
    return View(unitOfWork.CourseRepository.GetWithRawSql(query, id).Single());
}
```

In this case you could have used the `GetByID` method, but you're using the `GetWithRawSql` method to verify that the `GetWithRawSQL` method works.

Run the Details page to verify that the select query works (select the **Course** tab and then **Details** for one course).

Calling a Query that Returns Other Types of Objects

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. The code that does this in *HomeController.cs* uses LINQ:

```
var data = from student in db.Students
           group student by student.EnrollmentDate into dateGroup
           select new EnrollmentDateGroup()
           {
               EnrollmentDate = dateGroup.Key,
               StudentCount = dateGroup.Count()
           };
```

Suppose you want to write the code that retrieves this data directly in SQL rather than using LINQ. To do that you need to run a query that returns something other than entity objects, which means you need to use the `Database.SqlQuery` method.

In *HomeController.cs*, replace the LINQ statement in the `About` method with the following code:

```
var query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount "
    + "FROM Person "
    + "WHERE EnrollmentDate IS NOT NULL "
    + "GROUP BY EnrollmentDate";
var data = db.Database.SqlQuery<EnrollmentDateGroup>(query);
```

Run the About page. It displays the same data it did before.

Calling an Update Query

Suppose Contoso University administrators want to be able to perform bulk changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that allows the user to specify a factor by which to change the number of credits for all courses, and you'll make the change by executing a SQL `UPDATE` statement. The web page will look like the following illustration:

In the previous tutorial you used the generic repository to read and update `Course` entities in the `Course` controller. For this bulk update operation, you need to create a new repository method that isn't in the generic repository. To do that, you'll create a dedicated `CourseRepository` class that derives from the `GenericRepository` class.

In the *DAL* folder, create *CourseRepository.cs* and replace the existing code with the following code:

```
using System;
using ContosoUniversity.Models;

namespace ContosoUniversity.DAL
{
    public class CourseRepository : GenericRepository<Course>
    {
        public CourseRepository(SchoolContext context)
            : base(context)
        {
        }

        public int UpdateCourseCredits(int multiplier)
        {
            return context.Database.ExecuteSqlCommand("UPDATE Course SET Credits = Credits * {0}",
multiplier);
        }

    }
}
```

In *UnitOfWork.cs*, change the `Course` repository type from `GenericRepository<Course>` to `CourseRepository:`

```
private CourseRepository courseRepository;
```

```
public CourseRepository CourseRepository
{
    get
    {

        if (this.courseRepository == null)
        {
            this.courseRepository = new CourseRepository(context);
        }
        return courseRepository;
    }
}
```

In *CourseController.cs*, add an `UpdateCourseCredits` method:

```
public ActionResult UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewBag.RowsAffected = unitOfWork.CourseRepository.UpdateCourseCredits(multiplier.Value);
    }
    return View();
}
```

This method will be used for both `HttpGet` and `HttpPost`. When the `HttpGet` `UpdateCourseCredits` method runs, the `multiplier` variable will be null and the view will display an empty text box and a submit button, as shown in the preceding illustration.

When the **Update** button is clicked and the `HttpPost` method runs, `multiplier` will have the value entered in the text box. The code then calls the repository `UpdateCourseCredits` method, which returns the number of affected rows, and that value is stored in the `ViewBag` object. When the view receives the number of affected rows in the `ViewBag` object, it displays that number instead of the text box and submit button, as shown in the following illustration:

Create a view in the *Views\Course* folder for the Update Course Credits page:

In *Views\Course\UpdateCourseCredits.cshtml*, replace the template code with the following code:

```
@model ContosoUniversity.Models.Course

@{
    ViewBag.Title = "UpdateCourseCredits";
}

<h2>Update Course Credits</h2>

@if (ViewBag.RowsAffected == null)
{
    using (Html.BeginForm())
    {
        <p>
            Enter a number to multiply every course's credits by: @Html.TextBox("multiplier")
        </p>
        <p>
            <input type="submit" value="Update" />
        </p>
    }
}
@if (ViewBag.RowsAffected != null)
{
    <p>
        Number of rows updated: @ViewBag.RowsAffected
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:50205/Course/UpdateCourseCredits`). Enter a number in the text box:

Click **Update**. You see the number of rows affected:

Click **Back to List** to see the list of courses with the revised number of credits.

For more information about raw SQL queries, see Raw SQL Queries on the Entity Framework team blog.

No-Tracking Queries

When a database context retrieves database rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can specify whether the context tracks entity objects for a query by using the `AsNoTracking` method. Typical scenarios in which you might want to do that include the following:

- The query retrieves such a large volume of data that turning off tracking might noticeably enhance performance.
- You want to attach an entity in order to update it, but you earlier retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to prevent this from happening is to use the `AsNoTracking` option with the earlier query.

In this section you'll implement business logic that illustrates the second of these scenarios. Specifically, you'll enforce a business rule that says that an instructor can't be the administrator of more than one department.

In *DepartmentController.cs*, add a new method that you can call from the `Edit` and `Create` methods to make sure that no two departments have the same administrator:

```
private void ValidateOneAdministratorAssignmentPerInstructor(Department department)
{
    if (department.PersonID != null)
    {
        var duplicateDepartment = db.Departments
            .Include("Administrator")
            .Where(d => d.PersonID == department.PersonID)
            .FirstOrDefault();
        if (duplicateDepartment != null && duplicateDepartment.DepartmentID != department.DepartmentID)
        {
            var errorMessage = String.Format(
                "Instructor {0} {1} is already administrator of the {2} department.",
                duplicateDepartment.Administrator.FirstMidName,
                duplicateDepartment.Administrator.LastName,
                duplicateDepartment.Name);
            ModelState.AddModelError(string.Empty, errorMessage);
        }
    }
}
```

Add code in the `try` block of the `HttpPost` `Edit` method to call this new method if there are no validation errors. The `try` block now looks like the following example:

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult Edit(
   [Bind(Include = "DepartmentID, Name, Budget, StartDate, RowVersion, PersonID")]
    Department department)
{
   try
   {
      if (ModelState.IsValid)
      {
         ValidateOneAdministratorAssignmentPerInstructor(department);
      }

      if (ModelState.IsValid)
      {
         db.Entry(department).State = EntityState.Modified;
         db.SaveChanges();
         return RedirectToAction("Index");
      }
   }
   catch (DbUpdateConcurrencyException ex)
   {
      var entry = ex.Entries.Single();
      var clientValues = (Department)entry.Entity;
```

Run the Department Edit page and try to change a department's administrator to an instructor who is already the administrator of a different department. You get the expected error message:

Now run the Department Edit page again and this time change the **Budget** amount. When you click **Save**, you see an error page:

The exception error message is "

```
An object with the same key already exists in the ObjectStateManager. The ObjectStateManager cannot track
multiple objects with the same key.
```

" This happened because of the following sequence of events:

- The `Edit` method calls the `ValidateOneAdministratorAssignmentPerInstructor` method, which retrieves all departments that have Kim Abercrombie as their administrator. That causes the English department to be read. Because that's the department being edited, no error is reported. As a result of this read operation, however, the English department entity that was read from the database is now being tracked by the database context.
- The `Edit` method tries to set the `Modified` flag on the English department entity created by the MVC model binder, but that fails because the context is already tracking an entity for the English department.

One solution to this problem is to keep the context from tracking in-memory department entities retrieved by the validation query. There's no disadvantage to doing this, because you won't be updating this entity or reading it again in a way that would benefit from it being cached in memory.

In *DepartmentController.cs*, in the `ValidateOneAdministratorAssignmentPerInstructor` method, specify no tracking, as shown in the following:

```
var duplicateDepartment = db.Departments
    .Include("Administrator")
    .Where(d => d.PersonID == department.PersonID)
    .AsNoTracking()
    .FirstOrDefault();
```

Repeat your attempt to edit the **Budget** amount of a department. This time the operation is successful, and the site returns as expected to the Departments Index page, showing the revised budget value.

Examining Queries Sent to the Database

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. To do this, you can examine a query variable in the debugger or call the query's `ToString` method. To try this out, you'll look at a simple query and then look at what happens to it as you add options such eager loading, filtering, and sorting.

In *Controllers/CourseController*, replace the `Index` method with the following code:

```
public ViewResult Index()
{
    var courses = unitOfWork.CourseRepository.Get();
    return View(courses.ToList());
}
```

Now set a breakpoint in *GenericRepository.cs* on the `return query.ToList();` and the `return orderBy(query).ToList();` statements of the `Get` method. Run the project in debug mode and select the Course Index page. When the code reaches the breakpoint, examine the `query` variable. You see the query that's sent to SQL Server. It's a simple `Select` statement:

```
{SELECT
[Extent1].[CourseID] AS [CourseID],
[Extent1].[Title] AS [Title],
[Extent1].[Credits] AS [Credits],
[Extent1].[DepartmentID] AS [DepartmentID]
FROM [Course] AS [Extent1]}
```

Queries can be too long to display in the debugging windows in Visual Studio. To see the entire query, you can copy the variable value and paste it into a text editor:

Now you'll add a drop-down list to the Course Index page so that users can filter for a particular department. You'll sort the courses by title, and you'll specify eager loading for the `Department` navigation property. In *CourseController.cs*, replace the `Index` method with the following code:

```
public ActionResult Index(int? SelectedDepartment)
{
    var departments = unitOfWork.DepartmentRepository.Get(
        orderBy: q => q.OrderBy(d => d.Name));
    ViewBag.SelectedDepartment = new SelectList(departments, "DepartmentID", "Name", SelectedDepartment);

    int departmentID = SelectedDepartment.GetValueOrDefault();
    return View(unitOfWork.CourseRepository.Get(
        filter: d => !SelectedDepartment.HasValue || d.DepartmentID == departmentID,
        orderBy: q => q.OrderBy(d => d.CourseID),
        includeProperties: "Department"));
}
```

The method receives the selected value of the drop-down list in the `SelectedDepartment` parameter. If nothing is selected, this parameter will be null.

A `SelectList` collection containing all departments is passed to the view for the drop-down list. The parameters passed to the `SelectList` constructor specify the value field name, the text field name, and the selected item.

For the `Get` method of the `Course` repository, the code specifies a filter expression, a sort order, and eager loading for the `Department` navigation property. The filter expression always returns `true` if nothing is selected in the drop-down list (that is, `SelectedDepartment` is null).

In *Views\Course\Index.cshtml*, immediately before the opening `table` tag, add the following code to create the drop-down list and a submit button:

```
@using (Html.BeginForm())
{
    <p>Select Department: @Html.DropDownList("SelectedDepartment","All")
    <input type="submit" value="Filter" /></p>
}
```

With the breakpoints still set in the `GenericRepository` class, run the Course Index page. Continue through the first two times that the code hits a breakpoint, so that the page is displayed in the browser. Select a department from the drop-down list and click **Filter**:

This time the first breakpoint will be for the departments query for the drop-down list. Skip that and view the `query` variable the next time the code reaches the breakpoint in order to see what the `Course` query now looks like. You'll see something like the following:

```
{SELECT
[Extent1].[CourseID] AS [CourseID],
[Extent1].[Title] AS [Title],
[Extent1].[Credits] AS [Credits],
[Extent1].[DepartmentID] AS [DepartmentID],
[Extent2].[DepartmentID] AS [DepartmentID1],
[Extent2].[Name] AS [Name],
[Extent2].[Budget] AS [Budget],
[Extent2].[StartDate] AS [StartDate],
[Extent2].[PersonID] AS [PersonID],
[Extent2].[Timestamp] AS [Timestamp]
FROM  [Course] AS [Extent1]
INNER JOIN [Department] AS [Extent2] ON [Extent1].[DepartmentID] = [Extent2].[DepartmentID]
WHERE (@p__linq__0 IS NULL) OR ([Extent1].[DepartmentID] = @p__linq__1)}
```

You can see that the query is now a `JOIN` query that loads `Department` data along with the `Course` data, and that it includes a `WHERE` clause.

Working with Proxy Classes

When the Entity Framework creates entity instances (for example, when you execute a query), it often creates them as instances of a dynamically generated derived type that acts as a proxy for the entity. This proxy overrides some virtual properties of the entity to insert hooks for performing actions automatically when the property is accessed. For example, this mechanism is used to support lazy loading of relationships.

Most of the time you don't need to be aware of this use of proxies, but there are exceptions:

- In some scenarios you might want to prevent the Entity Framework from creating proxy instances. For example, serializing non-proxy instances might be more efficient than serializing proxy instances.
- When you instantiate an entity class using the `new` operator, you don't get a proxy instance. This means you don't get functionality such as lazy loading and automatic change tracking. This is typically okay; you generally don't need lazy loading, because you're creating a new entity that isn't in the database, and you generally don't need change tracking if you're explicitly marking the entity as `Added`. However, if you do need lazy loading and you need change tracking, you can create new entity instances with proxies using the `Create` method of the `DbSet` class.
- You might want to get an actual entity type from a proxy type. You can use the `GetObjectType` method of the `ObjectContext` class to get the actual entity type of a proxy type instance.

For more information, see Working with Proxies on the Entity Framework team blog.

Disabling Automatic Detection of Changes

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity was queried or attached. Some of the methods that cause automatic change detection are the following:

- `DbSet.Find`
- `DbSet.Local`
- `DbSet.Remove`
- `DbSet.Add`
- `DbSet.Attach`
- `DbContext.SaveChanges`
- `DbContext.GetValidationErrors`
- `DbContext.Entry`
- `DbChangeTracker.Entries`

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the AutoDetectChangesEnabled property. For more information, see Automatically Detecting Changes.

Disabling Validation When Saving Changes

When you call the `SaveChanges` method, by default the Entity Framework validates the data in all properties of all changed entities before updating the database. If you've updated a large number of entities and you've already validated the data, this work is unnecessary and you could make the process of saving the changes take less time by temporarily turning off validation. You can do that using the ValidateOnSaveEnabled property. For more information, see Validation.

Summary

This completes this series of tutorials on using the Entity Framework in an ASP.NET MVC application. Links to other Entity Framework resources can be found in the ASP.NET Data Access Content Map.

For more information about how to deploy your web application after you've built it, see ASP.NET Deployment Content Map in the MSDN Library.

For information about other topics related to MVC, such as authentication and authorization, see the MVC Recommended Resources.

Acknowledgments

- Tom Dykstra wrote the original version of this tutorial and is a senior programming writer on the Microsoft Web Platform and Tools Content Team.
- Rick Anderson (twitter @RickAndMSFT) co-authored this tutorial and did most of the work updating it for EF 5 and MVC 4. Rick is a senior programming writer for Microsoft focusing on Azure and MVC.
- Rowan Miller and other members of the Entity Framework team assisted with code reviews and helped debug many issues with migrations that arose while we were updating the tutorial for EF 5.

VB

When the tutorial was originally produced, we provided both C# and VB versions of the completed download project. With this update we are providing a C# downloadable project for each chapter to make it easier to get started anywhere in the series, but due to time limitations and other priorities we did not do that for VB. If you build a VB project using these tutorials and would be willing to share that with others, please let us know.

Errors and Workarounds

Cannot create/shadow copy

Error Message:

Cannot create/shadow copy 'DotNetOpenAuth.OpenId' when that file already exists.

Solution:

Wait a few seconds and refresh the page.

Update-Database not recognized

Error Message:

The term 'Update-Database' is not recognized as the name of a cmdlet, function, script file, or operable program. Check the spelling of the name, or if a path was included, verify that the path is correct and try again.(From the `Update-Database` command in the PMC.)

Solution:

Exit Visual Studio. Reopen project and try again.

Validation failed

Error Message:

Validation failed for one or more entities. See 'EntityValidationErrors' property for more details. (From the `Update-Database` command in the PMC.)

Solution:

One cause of this problem is validation errors when the `Seed` method runs. See Seeding and Debugging Entity Framework (EF) DBs for tips on debugging the `Seed` method.

HTTP 500.19 error

Error Message:

HTTP Error 500.19 - Internal Server Error
The requested page cannot be accessed because the related configuration data for the page is invalid.

Solution:

One way you can get this error is from having multiple copies of the solution, each of them using the same port number. You can usually solve this problem by exiting all instances of Visual Studio, then restarting the project your working on. If that doesn't work, try changing the port number. Right click on the project file and then click properties. Select the **Web** tab and then change the port number in the **Project Url** text box.

Error locating SQL Server instance

Error Message:

A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution:

Check connection string. If you have manually deleted the database, change the name of the database in the construction string.

Building the Chapter Downloads for the EF 5 MVC 4 Tutorials

2/20/2020 • 2 minutes to read • Edit Online

by Rick Anderson

Download Completed Project

> The Contoso University sample web application demonstrates how to create ASP.NET MVC 4 applications using the Entity Framework 5 Code First and Visual Studio 2012. For information about the tutorial series, see the first tutorial in the series.

Building the Chapter Downloads

1. Download and unzip the project sample zip file. In the unzipped download package, you will find additional zip files, one for the completion of each chapter.
2. Right click on the desired zip file, click **Properties**, and click the **Unblock** button.

3. Unzip the file.
4. Double-click the *CUx.sln* file to launch Visual Studio.
5. From the **Tools** menu, click **NuGet Package Manager**, then **Package Manager Console**.

6. In the Package Manager Console (PMC), click **Restore**.

7. Exit Visual Studio.

8. Restart Visual Studio, opening the solution file you closed in the step above.

9. In the Package Manager Console (PMC), enter the `Update-Database` command:

> **NOTE**
>
> If you get the following error:
>
> *The term 'Update-Database' is not recognized as the name of a cmdlet, function, script file, or operable program. Check the spelling of the name, or if a path was included, verify that the path is correct and try again.*
>
> Exit and restart Visual Studio.

Each migration will run, then the seed method will run. You can now run the app.

Package Manager Console
Package source: NuGet official package source
PM> Update-Database
Specify the '-Verbose' flag to view the SQL statements being applied to the target database.
Applying code-based migrations: [201306242243244_InitialCreate, 201306270046282_MaxLengthOnNames, 201306270053243_ColumnFirstName, 201307032354328_Chap4].
Applying code-based migration: 201306242243244_InitialCreate.
Applying code-based migration: 201306270046282_MaxLengthOnNames.
Applying code-based migration: 201306270053243_ColumnFirstName.
Applying code-based migration: 201307032354328_Chap4.
Running Seed method.

What's New in ASP.NET MVC 4

2/20/2020 • 41 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

ASP.NET MVC 4 is a framework for building scalable, standards-based web applications using well-established design patterns and the power of the ASP.NET and the .NET framework. This new, fourth version of the framework focuses on making mobile web application development easier.

To begin with, when you create a new ASP.NET MVC 4 project there is now a mobile application project template you can use to build a standalone app specifically for mobile devices. Additionally, ASP.NET MVC 4 integrates with jQuery Mobile through a jQuery.Mobile.MVC NuGet package. jQuery Mobile is an HTML5-based framework for developing web apps that are compatible with all popular mobile device platforms, including Windows Phone, iPhone, Android and so on. However, if you need specialization, ASP.NET MVC 4 also enables you to serve different views for different devices and provide device-specific optimizations.

In this hands-on lab, you will start with the ASP.NET MVC 4 "Internet Application" project template to create a Photo Gallery application. You will progressively enhance the app using jQuery Mobile and ASP.NET MVC 4's new features to make it compatible with different mobile devices and desktop web browsers. You will also learn about new code recipes for code generation and how ASP.NET MVC 4 makes it easier for you to write asynchronous action methods by supporting Task<ActionResult> return types.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at What's New in Web Forms in ASP.NET 4.5.

Objectives

In this hands-on lab, you will learn how to:

- Take advantage of the enhancements to the ASP.NET MVC project templates-including the new mobile application project template
- Use the HTML5 viewport attribute and CSS media queries to improve the display on mobile devices
- Use jQuery Mobile for progressive enhancements and for building touch-optimized web UI
- Create mobile-specific views
- Use the view-switcher component to toggle between mobile and desktop views in the application
- Create asynchronous controllers using task support

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix B for instructions on how to install it).
- ASP.NET MVC 4 (included in the Microsoft Visual Studio 2012 installation)
- Windows Phone Emulator (included in the Windows Phone 7.1.1 SDK)
- Optional - WebMatrix 2 with **Electric Plum iPhone Simulator** extension (only for Exercise 3 used to browse the web application with an iPhone simulator)

Setup

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of that code is provided as Visual Studio Code Snippets, which you can use from within Visual Studio to avoid having to add it manually.

To install the code snippets:

1. Open a Windows Explorer window and browse to the lab's **Source\Setup** folder.
2. Double-click the **Setup.cmd** file in this folder to install the Visual Studio code snippets.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix A: Using Code Snippets".

Exercises

This hands-on lab includes the following exercises:

1. New ASP.NET MVC 4 Project Templates
2. Creating the Photo Gallery Web Application
3. Adding Support for Mobile Devices
4. Using Asynchronous Controllers

> **NOTE**
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **60 minutes**.

Exercise 1: New ASP.NET MVC 4 Project Templates

In this exercise, you will explore the enhancements in the ASP.NET MVC 4 Project templates. In addition to the Internet Application template, already present in MVC 3, this version now includes a separate template for Mobile applications. First, you will look at some relevant features of each of the templates. Then, you will work on rendering your page properly on the different platforms by using the right approach.

Task 1 - Exploring the Internet Application Template

1. Open **Visual Studio**.
2. Select the **File | New | Project** menu command. In the **New Project** dialog, select the **Visual C# | Web** template on the left pane tree, and choose **ASP.NET MVC 4 Web Application.** Name the project **PhotoGallery**, select a location (or leave the default) and click **OK**.

   > **NOTE**
   > You will later customize the PhotoGallery ASP.NET MVC 4 solution you are now creating.

Creating a new project

3. In the **New ASP.NET MVC 4 Project** dialog, select the **Internet Application** project template and click **OK**. Make sure you have selected Razor as the view engine.

Creating a new ASP.NET MVC 4 Internet Application

> **NOTE**
>
> Razor syntax has been introduced in ASP.NET MVC 3. Its goal is to minimize the number of characters and keystrokes required in a file, enabling a fast and fluid coding workflow. Razor leverages existing C# / VB (or other) language skills and delivers a template markup syntax that enables an awesome HTML construction workflow.

4. Press **F5** to run the solution and see the renewed templates. You can check out the following features:

Modern-style templates

The templates have been renewed, providing more modern-looking styles.

ASP.NET MVC 4 restyled templates

New Contact page

Adaptive Rendering

Check out resizing the browser window and notice how the page layout dynamically adapts to the new window size. These templates use the adaptive rendering technique to render properly in both desktop and

mobile platforms without any customization.

ASP.NET MVC 4 project template in different browser sizes

Richer UI with JavaScript

Another enhancement to default project templates is the use of JavaScript to provide a more interactive JavaScript. The Login and Register links used in the template exemplify how to use the jQuery Validations to validate the input fields from client-side.

jQuery Validation

> **NOTE**
>
> Notice the two log in sections, in the first section you can log in using a registered account from the site and in the second section you can alternatively log in using another authentication service like google (disabled by default).

5. Close the browser to stop the debugger and return to Visual Studio.

6. Open the file **AuthConfig.cs** located under the **App_Start** folder.

7. Remove the comment from the last line to register Google client for *OAuth* authentication.

```
public static class AuthConfig
{
    public static void RegisterAuth()
    {
        // To let users of this site log in using their accounts from other sites such as Microsoft,
Facebook, and Twitter,
        // you must update this site. For more information visit https://go.microsoft.com/fwlink/?
LinkID=252166

        //OAuthWebSecurity.RegisterMicrosoftClient(
        //    clientId: "",
        //    clientSecret: "");

        //OAuthWebSecurity.RegisterTwitterClient(
        //    consumerKey: "",
        //    consumerSecret: "");

        //OAuthWebSecurity.RegisterFacebookClient(
        //    appId: "",
        //    appSecret: "");

        OAuthWebSecurity.RegisterGoogleClient();
    }
}
```

> **NOTE**
>
> Notice you can easily enable authentication using any OpenID or OAuth service like Facebook, Twitter, Microsoft, etc.

8. Press **F5** to run the solution and navigate to the login page.

9. Select **Google** service to log in.

Selecting the log in service

10. Log in using your Google account.

11. Allow the site (localhost) to retrieve information from Google account.

12. Finally, you will have to register in the site to associate the Google account.

Associating your Google account 13. Close the browser to stop the debugger and return to Visual Studio. 14. Now explore the solution to check out some other new features introduced by ASP.NET MVC 4 in the project template.

The ASP.NET MVC 4 Internet Application Project Template

```
- **HTML 5 Markup**

   Browse template views to find out the new theme markup.

   ![New template, using Razor and HTML5 markup About.cshtml.](whats-new-in-aspnet-mvc-4/_static/image10.png
"New template, using Razor and HTML5 markup About.cshtml.")

   *New template, using Razor and HTML5 markup (About.cshtml).*
- **Updated JavaScript libraries**

   The ASP.NET MVC 4 default template now includes KnockoutJS, a JavaScript MVVM framework that lets you
create rich and highly responsive web applications using JavaScript and HTML. Like in MVC3, jQuery and jQuery
UI libraries are also included in ASP.NET MVC 4.

 > [!NOTE]
 > You can get more information about KnockOutJS library in this link: [[http://learn.knockoutjs.com/]
(http://learn.knockoutjs.com/)](http://learn.knockoutjs.com/). Additionally, you can learn about jQuery and
jQuery UI in [[http://docs.jquery.com/](http://docs.jquery.com/)](http://docs.jquery.com/).
```

Task 2 - Exploring the Mobile Application Template

ASP.NET MVC 4 facilitates the development of websites for mobile and tablet browsers. This template has the same application structure as the Internet Application template (notice that the controller code is practically identical), but its style was modified to render properly in touch-based mobile devices.

1. Select the **File | New | Project** menu command. In the **New Project** dialog, select the **Visual C# | Web** template on the left pane tree, and choose the **ASP.NET MVC 4 Web Application.** Name the project **PhotoGallery.Mobile**, select a location (or leave the default), select "Add to solution" and click **OK**.

2. In the **New ASP.NET MVC 4 Project** dialog, select the **Mobile Application** project template and click **OK**. Make sure you have selected Razor as the view engine.

Creating a new ASP.NET MVC 4 Mobile Application

3. Now you are able to explore the solution and check out some of the new features introduced by the ASP.NET MVC 4 solution template for mobile:

   - **jQuery Mobile Library**

     The Mobile Application project template includes the jQuery Mobile library, which is an open source library for mobile browser compatibility. jQuery Mobile applies progressive enhancement to mobile browsers that support CSS and JavaScript. Progressive enhancement enables all browsers to display the basic content of a web page, while it only enables the most powerful browsers to display the rich content. The JavaScript and CSS files, included in the jQuery Mobile style, help mobile browsers to fit the content in the screen without making any change in the page markup.

jQuery mobile library included in the template

   - **HTML5 based markup**

```
@using (Html.BeginForm()) {
    @Html.ValidationSummary()

    <ul data-role="listview" data-inset="true">
        <li data-role="list-divider">Details</li>

        <li data-role="fieldcontain">
            @Html.LabelFor(m => m.UserName)
            @Html.TextBoxFor(m => m.UserName)
        </li>

        <li data-role="fieldcontain">
            @Html.LabelFor(m => m.Password)
            @Html.PasswordFor(m => m.Password)
        </li>

        <li data-role="fieldcontain">
```

```
<ul data-role="listview" data-inset="true">
    <li data-role="list-divider">Navigation</li>
    <li>@Html.ActionLink("About", "About", "Home")</li>
    <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
</ul>
```

```
            <input type="submit" value="Log in" />
        </li>
    </ul>
}
```

Mobile application template using HTML5 markup, (Login.cshtml and index.cshtml)

4. Press **F5** to run the solution.

5. Open the **Windows Phone 7 Emulator**.

6. In the phone start screen, open Internet Explorer. Check out the URL where the desktop application started and browse to that URL from the phone (e.g. `http://localhost:[PortNumber]/`).

7. Now you are able to enter the login page or check out the about page. Notice that the style of the website is based on the new Metro app for mobile. The ASP.NET MVC 4 project template is correctly displayed on mobile devices, making sure all the elements of the page are visible and enabled. Notice that the links on the header are big enough to be clicked or tapped.

Project template pages in a mobile device

8. The new template also uses the **Viewport meta tag**. Most mobile browsers define a width for a virtual browser window or "viewport", which is larger than the actual width of the mobile device. This enables mobile browsers to display the entire web page inside the virtual display. The **Viewport meta tag** allows web developers to set the width, height and scale of the browser area on mobile devices . The ASP.NET MVC 4 template for Mobile Applications sets the viewport to the device width ("width=device-width") in the layout template (*Views\Shared_Layout.cshtml*), so that all the pages will have their viewport set to the device screen width. Notice that the Viewport meta tag will not change the default browser view.

9. Open **_Layout.cshtml**, located in the **Views | Shared** folder, and comment the Viewport meta tag. Run the application, if not already opened, and check out the differences.

```
...
 <meta charset="utf-8" />
 <title>@ViewBag.Title</title>
 @* <meta name="viewport" content="width=device-width" /> *@
...
```

The site after commenting the viewport meta tag 10. In Visual Studio, press **SHIFT + F5** to stop debugging the application. 11. Uncomment the viewport meta tag.

```
...
 <meta charset="utf-8" />
 <title>@ViewBag.Title</title>
   <meta name="viewport" content="width=device-width" />
...
```

Task 3 - Using Adaptive Rendering

In this task, you will learn another method to render a Web page correctly on mobile devices and Web browsers at the same time without any customization. You have already used Viewport meta tag with a similar purpose. Now you will meet another powerful method: *adaptive rendering*.

Adaptive rendering is a technique that uses **CSS3 media queries** to customize the style applied to a page. Media queries define conditions inside a style sheet, grouping CSS styles under a certain condition. Only when the condition is true, the style is applied to the declared objects.

The flexibility provided by the adaptive rendering technique enables any customization for displaying the site on different devices. You can define as many styles as you want on a single style sheet without writing logic code to choose the style. Therefore, it is a very neat way of adapting page styles, as it reduces the amount of duplicated code and logic for rendering purposes. On the other hand, bandwidth consumption would increase, as the size of your CSS files could grow marginally.

By using the adaptive rendering technique, your site will be **displayed properly, regardless of the browser.** However, you should consider if the bandwidth extra load is a concern.

> **NOTE**
> The basic format of a media query is: @media [Scope: all | handheld | print | projection | screen] ([property:value] and ... [property:value])

Examples of media queries: >**@media all and (max-width: 1000px) and (min-width: 700px) {}:** For all the resolutions between 700px and 1000px.

> **@media screen and (min-width: 400px) and (max-width: 700px) { ... }:** Only for screens. The resolution must be between 400 and 700px.
>
> **@media handheld and (min-width: 20em), screen and (min-width: 20em) { ... }:** For

> handhelds(mobile and devices) and screens. The minimum width must be greater than 20em.
>
> You can find more information about this on the W3C site.

You will now explore how the adaptive rendering works, improving the readability of the ASP.NET MVC 4 default website template.

1. Open the **PhotoGallery.sln** solution you have created at Task 1 and select the **PhotoGallery** project. Press **F5** to run the solution.

2. Resize the browser's width, setting the windows to half or to less than a quarter of its original size. Notice what happens with the items in the header: Some elements will not appear in the visible area of the header.

3. Open **Site.css** file from the Visual Studio Solution explorer, located in **Content** project folder. Press **CTRL + F** to open Visual Studio integrated search, and write `@media` to locate the **CSS media query**.

   The media query condition defined in this template works in this way: When the browser's window size is below **850 px**, the CSS rules applied are the ones defined inside this media block.

   Locating the media query

4. Replace the max-width attribute value set in 850 px with **10px**, in order to disable the adaptive rendering, and press **CTRL + S** to save the changes. Return to the browser and press **CTRL + F5** to refresh the page with the changes you have made. Notice the differences in both pages when adjusting the width of the window.

In the left, the page is applying the @media style, in the right, the style is omitted

Now, let's check out what happens on mobile devices:

In the left, the page is applying the @media style, in the right, the style is omitted

Although you will notice that the changes when the page is rendered in a Web browser are not very significant, when using a mobile device the differences become more obvious. On the left side of the image, we can see that the custom style improved the readability.

Adaptive rendering can be used in many more scenarios, making it easier to apply conditional styling to a Web site and solving common style issues with a neat approach.

The Viewport meta tag and CSS media queries are not specific to ASP.NET MVC 4, so you can take advantage of these features in any web application.

5. In Visual Studio, press **SHIFT + F5** to stop debugging the application.

Exercise 2: Creating the Photo Gallery Web Application

In this exercise, you will work on a Photo Gallery application to display photos. You will start with the ASP.NET MVC 4 project template, and then you will add a feature to retrieve photos from a service and display them in the home page.

In the following exercise, you will update this solution to enhance the way it is displayed on mobile devices.

Task 1 - Creating a Mock Photo Service

In this task, you will create a mock of the photo service to retrieve the content that will be displayed in the gallery. To do this, you will add a new controller that will simply return a JSON file with the data of each photo.

1. Open **Visual Studio** if not already opened.

2. Select the **File | New | Project** menu command. In the **New Project** dialog, select the **Visual C# | Web** template on the left pane tree, and choose **ASP.NET MVC 4 Web Application.** Name the project **PhotoGallery**, select a location (or leave the default) and click **OK**. Alternatively, you can continue working from your existing ASP.NET MVC 4 **Internet Application** solution from **Exercise 1** and skip the next step.

3. In the **New ASP.NET MVC 4 Project** dialog box, select the **Internet Application** project template and click **OK**. Make sure you have Razor selected as the View Engine.

4. In the **Solution Explorer**, right-click the **App_Data** folder of your project, and select **Add | Existing Item**. Browse to the **Source\Assets\App_Data** folder of this lab and add the **Photos.json** file.

5. Create a new controller with the name **PhotoController**. To do this, right-click on the **Controllers** folder, go to **Add** and select **Controller.** Complete the controller name, leave the **Empty MVC controller** template and click **Add**.

Adding the PhotoController

6. Replace the **Index** method with the following **Gallery** action, and return the content from the JSON file you have recently added to the project.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex02 - Gallery Action*)

```
public class PhotoController : Controller
{
   public ActionResult Gallery()
   {
      return this.File("~/App_Data/Photos.json", "application/json");
   }
}
```

7. Press **F5** to run the solution, and then browse to the following URL in order to test the mocked photo service: `http://localhost:[port]/photo/gallery` (the [port] value depends on the current port where the application was launched). The request to this URL should retrieve the content of the **Photos.json** file.

Testing the mocked photo service

In a real implementation you could use ASP.NET Web API to implement the Photo Gallery service. ASP.NET Web API is a framework that makes it easy to build HTTP services that reach a broad range of clients, including browsers

and mobile devices. ASP.NET Web API is an ideal platform for building RESTful applications on the .NET Framework.

Task 2 - Displaying the Photo Gallery

In this task, you will update the Home page to show the photo gallery by using the mocked service you created in the first task of this exercise. You will add model files and update the gallery views.

1. In Visual Studio, press **SHIFT** + **F5** to stop debugging the application.
2. Create the **Photo** class in the **Models** folder. To do this, right-click on the **Models** folder, select **Add** and click **Class**. Then, set the name to **Photo.cs** and click **Add**.
3. Add the following members to the **Photo** class.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex02 - Photo model*)

```
public class Photo
{
    public string Title { get; set; }

    public string FileName { get; set; }

    public string Description { get; set; }

    public DateTime UploadDate { get; set; }
}
```

4. Open the **HomeController.cs** file from the **Controllers** folder.
5. Add the following using statements.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex02 - HomeController Usings*)

```
using System.Net.Http;
using System.Web.Script.Serialization;
using Newtonsoft.Json;
using PhotoGallery.Models;
```

6. Update the **Index** action to use **HttpClient** to retrieve the gallery data, and then use the **JavaScriptSerializer** to deserialize it to the view model.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex02 - Index Action*)

```
public ActionResult Index()
{
    var client = new HttpClient();
    var response = client.GetAsync(Url.Action("gallery", "photo", null, Request.Url.Scheme)).Result;
    var value = response.Content.ReadAsStringAsync().Result;

    var result = JsonConvert.DeserializeObject<List<Photo>>(value);

    return View(result);
}
```

7. Open the **Index.cshtml** file located under the **Views\Home** folder and replace all the content with the following code.

   This code loops through all the photos retrieved from the service and displays them into an unordered list.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex02 - Photo List*)

```
@model List<PhotoGallery.Models.Photo>
@{
    ViewBag.Title = "Photo Gallery";
}

<ul class="thumbnails">
    @foreach (var photo in Model)
    {
        <li class="item">
            <a href="@Url.Content("~/photos/" + photo.FileName)">
                <img alt="@photo.Description" src="@Url.Content("~/photos/" + photo.FileName)"
class="thumbnail-border" width="180" />
            </a>
                <span class="image-overlay">@photo.Title</span>
        </li>
    }
</ul>
```

8. In the **Solution Explorer**, right-click the **Content** folder of your project, and select **Add | Existing Item**. Browse to the **Source\Assets\Content** folder of this lab and add the **Site.css** file. You will have to confirm its replacement. If you have the **Site.css** file open, you will have to confirm to reload the file also.

9. Open File Explorer and copy the entire **Photos** folder located under the **Source\Assets** folder of this lab to the root folder of your project in Solution Explorer.

10. Run the application. You should now see the home page displaying the photos in the gallery.

Photo Gallery

11. In Visual Studio, press **SHIFT** + **F5** to stop debugging the application.

Exercise 3: Adding support for mobile devices

One of the key updates in ASP.NET MVC 4 is the support for mobile development. In this exercise, you will explore ASP.NET MVC 4 new features for mobile applications by extending the PhotoGallery solution you have created in the previous exercise.

Task 1 - Installing jQuery Mobile in an ASP.NET MVC 4 Application

1. Open the **Begin** solution located at **Source/Ex3-MobileSupport/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open the **Package Manager Console** by clicking the **Tools** > **NuGet Package Manager** > **Package Manager Console** menu option.

Opening the NuGet Package Manager Console

3. In the Package Manager Console run the following command to install the **jQuery.Mobile.MVC** package.

jQuery Mobile is an open source library for building touch-optimized web UI. The jQuery.Mobile.MVC NuGet package includes helpers to use jQuery Mobile with an ASP.NET MVC 4 application.

> **NOTE**
>
> By running the following command, you will be downloading the jQuery.Mobile.MVC library from Nuget.

PM

```
Install-Package jQuery.Mobile.MVC
```

This command installs jQuery Mobile and some helper files, including the following:

- **Views/Shared/_Layout.Mobile.cshtml**: is a jQuery Mobile-based layout optimized for a smaller screen. When the website receives a request from a mobile browser, it will replace the original layout (_Layout.cshtml) with this one.
- A view-switcher component: consists of the **Views/Shared/_ViewSwitcher.cshtml** partial view and the **ViewSwitcherController.cs** controller. This component will show a link on mobile browsers to enable users to switch to the desktop version of the page.

Photo Gallery project with mobile support

4. Register the Mobile bundles. To do this, open the **Global.asax.cs** file and add the following line.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex03 - Register Mobile Bundles*)

```
protected void Application_Start()
{
     AreaRegistration.RegisterAllAreas();

     WebApiConfig.Register(GlobalConfiguration.Configuration);
     FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
     RouteConfig.RegisterRoutes(RouteTable.Routes);
     BundleConfig.RegisterBundles(BundleTable.Bundles);
     BundleMobileConfig.RegisterBundles(BundleTable.Bundles);
     AuthConfig.RegisterAuth();
}
```

5. Run the application using a desktop web browser.

6. Open the **Windows Phone 7 Emulator**, located in **Start Menu | All Programs | Windows Phone SDK 7.1 | Windows Phone Emulator.**

7. In the phone start screen, open Internet Explorer. Check out the URL where the application started and browse to that URL with the phone browser (e.g. `http://localhost:[PortNumber]/`).

   You will notice that your application will look different in the Windows Phone emulator, as the jQuery.Mobile.MVC has created new assets in your project that show views optimized for mobile devices.

Notice the message at the top of the phone, showing the link that switches to the Desktop view. Additionally, the **_Layout.Mobile.cshtml** layout that was created by the package you have installed is including a different layout in the application.

> **NOTE**
>
> So far, there is no link to get back to mobile view. It will be included in later versions.

Mobile view of the Photo Gallery Home page

8. In Visual Studio, press **SHIFT + F5** to stop debugging the application.

Task 2 - Creating Mobile Views

In this task, you will create a mobile version of the index view with content adapted for better appearance in mobile devices.

1. Copy the **Views\Home\Index.cshtml** view and paste it to create a copy, rename the new file to **Index.Mobile.cshtml**.

2. Open the new created **Index.Mobile.cshtml** view and replace the existing <ul> tag with this code. By doing this, you will be updating the <ul> tag with jQuery Mobile data annotations to use the mobile themes from jQuery.

```
<ul data-role="listview" data-inset="true" data-filter="true">
```

> **NOTE**
>
> Notice that:
>
> - The **data-role** attribute set to **listview** will render the list using the listview styles.
> - The **data-inset** attribute set to true will show the list with rounded border and margin.
> - The **data-filter** attribute set to **true** will generate a search box.
>
> You can learn more about jQuery Mobile conventions in the project documentation: http://jquerymobile.com/demos/1.1.1/

3. Press **CTRL + S** to save the changes.

4. Switch to the **Windows Phone Emulator** and refresh the site. Notice the new look and feel of the gallery list, as well as the new search box located on the top. Then, type a word in the search box (for instance, **Tulips**) to start a search in the photo gallery.

Gallery using listview style with filtering

To summarize, you have used the View Mobilizer recipe to create a copy of the Index view with the "mobile" suffix. This suffix indicates to ASP.NET MVC 4 that every request generated from a mobile device will use this copy of the index. Additionally, you have updated the mobile version of the Index view to use jQuery Mobile for enhancing the site look and feel in mobile devices.

5. Go back to Visual Studio and open **Site.Mobile.css** located under the **Content** folder.

6. Fix the positioning of the photo title to make it show at the right side of the image. To do this, add the following code to the **Site.Mobile.css** file.

   CSS

```
.ui-li .ui-btn-inner a.ui-link-inherit, .ui-li-static.ui-li {
    padding: 0px !important;
}

li.item span.image-overlay
{
    position:relative;
    left:100px;
    top:-40px;
    height:0px;
    display:block;
}
```

7. Press **CTRL + S** to save the changes.

8. Switch back to the **Windows Phone Emulator** and refresh the site. Notice the photo title is properly positioned now.

Title positioned on the right side of the image

Task 3 - jQuery Mobile Themes

Every layout and widget in jQuery Mobile is designed around a new object-oriented CSS framework that makes it possible to apply a complete unified visual design theme to sites and applications.

jQuery Mobile's default Theme includes 5 swatches that are given letters (a, b, c, d, e) for quick reference.

In this task, you will update the mobile layout to use a different theme than the default.

1. Switch back to Visual Studio.
2. Open the **_Layout.Mobile.cshtml** file located in **Views\Shared**.
3. Find the div element with the data-role set to "page" and update the **data-theme** to "**e**".

```
<div data-role="page" data-theme="e">
```

4. Press **CTRL + S** to save the changes.
5. Refresh the site in the **Windows Phone Emulator** and notice the new colors scheme.

Mobile layout with a different color scheme

Task 4 - Using the View-Switcher Component and the Browser Overriding Features

A convention for mobile-optimized web pages is to add a link whose text is something like Desktop view or Full site mode that lets users switch to a desktop version of the page. The jQuery.Mobile.MVC package includes a sample **view-switcher** component for this purpose used in the **_Layout.Mobile.cshtml** view.

Link to switch to Desktop View

The view switcher uses a new feature called **Browser Overriding**. This feature lets your application treat requests as if they were coming from a different browser (user agent) than the one they are actually coming from.

In this task, you will explore the sample implementation of a view-switcher added by jQuery.Mobile.MVC and the new browser overriding features in ASP.NET MVC 4.

1. Switch back to Visual Studio.
2. Open the **_Layout.Mobile.cshtml** view located under the **Views\Shared** folder and notice the view-switcher component being referenced as a partial view.

```
_Layout.Mobile.cshtml
        </script>
    </head>
<body>

    <div data-role="page" data-theme="e">
        @Html.Partial("_ViewSwitcher")

        <div data-role="header">
            <h1>@ViewBag.Title</h1>
        </div>

        <div data-role="content">
            @RenderSection("featured", false)
            @RenderBody()
        </div>

    </div>
```

Mobile layout using View-Switcher component

3. Open the **_ViewSwitcher.cshtml** partial view.

   The partial view uses the new method **ViewContext.HttpContext.GetOverriddenBrowser()** to determine the origin of the web request and show the corresponding link to switch either to the Desktop or Mobile views.

   The **GetOverriddenBrowser** method returns an **HttpBrowserCapabilitiesBase** instance that corresponds to the user agent currently set for the request (actual or overridden). You can use this value to get properties such as **IsMobileDevice**.

```
_ViewSwitcher.cshtml   _Layout.Mobile.cshtml
@if (Request.Browser.IsMobileDevice && Request.HttpMethod == "GET")
{
    <div class="view-switcher ui-bar-a">
        @if (ViewContext.HttpContext.GetOverriddenBrowser().IsMobileDevice)
        {
            @: Displaying mobile view
            @Html.ActionLink("Desktop view", "SwitchView", "ViewSwitcher", new { mobile = false, returnUrl =
        }
        else
        {
            @: Displaying desktop view
            @Html.ActionLink("Mobile view", "SwitchView", "ViewSwitcher", new { mobile = true, returnUrl = Re
        }
    </div>
}
```

ViewSwitcher partial view

4. Open the **ViewSwitcherController.cs** class located in the **Controllers** folder. Check out that SwitchView action is called by the link in the ViewSwitcher component, and notice the new HttpContext methods.

   - The **HttpContext.ClearOverriddenBrowser()** method removes any overridden user agent for the current request.

   - The **HttpContext.SetOverriddenBrowser()** method overrides the request's actual user agent value using the specified user agent.

```
ViewSwitcherController.cs
PhotoGallery.Controllers.ViewSwitcherController        SwitchView(bool mobile, string returnUrl)
using System.Web.Mvc;
using System.Web.WebPages;

namespace PhotoGallery.Controllers
{
    public class ViewSwitcherController : Controller
    {
        public RedirectResult SwitchView(bool mobile, string returnUrl) {
            if (Request.Browser.IsMobileDevice == mobile)
                HttpContext.ClearOverriddenBrowser();
            else
                HttpContext.SetOverriddenBrowser(mobile ? BrowserOverride.Mobile : BrowserOverride.Desktop);

            return Redirect(returnUrl);
        }
    }
}
```

   ViewSwitcher Controller

   Browser Overriding is a core feature of ASP.NET MVC 4, which is also available even if you do not install the jQuery.Mobile.MVC package. However, this feature affects only view, layout, and partial-view, and it does not affect any of the features that depend on the Request.Browser object.

Task 5 - Adding the View-Switcher in the Desktop View

In this task, you will update the desktop layout to include the view-switcher. This will allow mobile users to go back to the mobile view when browsing the desktop view.

1. Refresh the site in the **Windows Phone Emulator**.

2. Click on the **Desktop view** link at the top of the gallery. Notice there is no view-switcher in the desktop view to allow you return to the mobile view.

3. Go back to Visual Studio and open the **_Layout.cshtml** view.

4. Find the login section and insert a call to render the **_ViewSwitcher** partial view below the **_LogOnPartial** partial view. Then, press **CTRL + S** to save the changes.

```
<div class="float-right">
    <section id="login">
        @Html.Partial("_LogOnPartial")

        @Html.Partial("_ViewSwitcher")
    </section>
    <nav>
```

5. Press **CTRL + S** to save the changes.

6. Refresh the page in the Windows Phone Emulator and double-click the screen to zoom in. Notice that the home page now shows the **Mobile view** link that switches from mobile to desktop view.

View Switcher rendered in desktop view

7. Switch to the Mobile view again and browse to **About** page (http://localhost[port]/Home/About). Notice that, even if you haven't created an About.Mobile.cshtml view, the About page is displayed using the mobile layout (_Layout.Mobile.cshtml).

About page

8. Finally, open the site in a desktop Web browser. Notice that none of the previous updates has affected the desktop view.

PhotoGallery desktop view

Task 6 - Creating New Display Modes

The new display modes feature lets an application select views depending on the browser that is generating the request. For example, if a desktop browser requests the Home page, the application will return the **Views\Home\Index.cshtml** template. Then, if a mobile browser requests the Home page, the application will return the **Views\Home\Index.mobile.cshtml** template.

In this task, you will create a customized layout for iPhone devices, and you will have to simulate requests from iPhone devices. To do this, you can use either an iPhone emulator/simulator (like Electric Mobile Simulator) or a browser with add-ons that modify the user agent. For instructions on how to set the user agent string in an Safari browser to emulate an iPhone, see How to let Safari pretend it's IE in David Alison's blog.

Notice that this task is optional and you can continue throughout the lab without executing it.

1. In Visual Studio, press **SHIFT** + **F5** to stop debugging the application.
2. Open **Global.asax.cs** and add the following using statement.

```
using System.Web.WebPages;
```

3. Add the following highlighted code into the Application_Start method.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex03 - iPhone DisplayMode*)

```
protected void Application_Start()
{
    // ...

    DisplayModeProvider.Instance.Modes.Insert(0, new DefaultDisplayMode("iPhone")
    {
        ContextCondition = context =>
            context.Request.UserAgent != null &&
            context.Request.UserAgent.IndexOf("iPhone", StringComparison.OrdinalIgnoreCase) >= 0
    });
}
```

You have registered a new **DefaultDisplayMode named "iPhone"**, within the static **DisplayModeProvider.Instance.Modes** static list, that will be matched against each incoming request. If the incoming request contains the string "iPhone", ASP.NET MVC will find the views whose name contain the "iPhone" suffix. The 0 parameter indicates how specific is the new mode; for instance, this view is more specific than the general ".mobile" rule that matches requests from mobile devices.

After this code runs, when an iPhone browser generates a request, your application will use the **Views\Shared_Layout.iPhone.cshtml** layout you will create in the next steps.

> **NOTE**
> This way of testing the request for iPhone has been simplified for demo purposes and might not work as expected for every iPhone user agent string (for example test is case sensitive).

4. Create a copy of the **_Layout.Mobile.cshtml** file in the **Views\Shared** folder and rename the copy to "**_Layout.iPhone.cshtml**".
5. Open **_Layout.iPhone.cshtml** you created in the previous step.
6. Find the div element with the data-role attribute set to **page** and change the **data-theme** attribute to "**a**".

```
<body>
    <div data-role="page" data-theme="a">
        @Html.Partial("_ViewSwitcher")
...
```

Now you have 3 layouts in your ASP.NET MVC 4 application:

1. **_Layout.cshtml**: default layout used for desktop browsers.
2. **_Layout.mobile.cshtml**: default layout used for mobile devices.
3. **_Layout.iPhone.cshtml**: specific layout for iPhone devices, using a different color scheme to differentiate from _Layout.mobile.cshtml.
4. Press **F5** to run the application and browse the site in the **Windows Phone Emulator**.
5. Open an **iPhone simulator** (see Appendix C for instructions on how to install and configure an iPhone simulator), and browse to the site too. Notice that each phone is using the specific template.

Using different views for each mobile device

Exercise 4: Using Asynchronous Controllers

Microsoft .NET Framework 4.5 introduces new language features in C# and Visual Basic to provide a new foundation for asynchrony in .NET programming. This new foundation makes asynchronous programming similar to - and about as straightforward as - synchronous programming. You are now able to write asynchronous action methods in ASP.NET MVC 4 by using the **AsyncController** class. You can use asynchronous action methods for long-running, non-CPU bound requests. This avoids blocking the Web server from performing work while the request is being processed. The AsyncController class is typically used for long-running Web service calls.

This exercise explains the basics of asynchronous operation in ASP.NET MVC 4. If you want a deeper dive, you can check out the following article: [https://msdn.microsoft.com/library/ee728598%28v=vs.100%29.aspx] (https://msdn.microsoft.com/library/ee728598%28v=vs.100%29.aspx)

Task 1 - Implementing an Asynchronous Controller

1. Open the **Begin** solution located at **Source/Ex4-Async/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open the **HomeController.cs** class from the **Controllers** folder.

3. Add the following using statement.

```
using System.Threading.Tasks;
```

4. Update the **HomeController** class to inherit from **AsyncController**. Controllers that derive from AsyncController enable ASP.NET to process asynchronous requests, and they can still service synchronous

action methods.

```
public class HomeController : AsyncController
{
```

5. Add the **async** keyword to the **Index** method and make it return the type **Task<ActionResult>**.

```
public async Task<ActionResult> Index()
{
    ...
```

> **NOTE**
>
> The **async** keyword is one of the new keywords the .NET Framework 4.5 provides; it tells the compiler that this method contains asynchronous code. A **Task** object represents an asynchronous operation that may complete at some point in the future.

6. Replace the **client.GetAsync()** call with the full async version using await keyword as shown below.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex04 - GetAsync*)

```
public async Task<ActionResult> Index()
{
    var client = new HttpClient();
    var response = await client.GetAsync(Url.Action("gallery", "photo", null, Request.Url.Scheme));
    ...
```

> **NOTE**
>
> In the previous version, you were using the **Result** property from the **Task** object to block the thread until the result is returned (sync version).
>
> Adding the **await** keyword tells the compiler to asynchronously wait for the task returned from the method call. This means that the rest of the code will be executed as a callback only after the awaited method completes. Another thing to notice is that you do not need to change your try-catch block in order to make this work: the exceptions that happen in background or in foreground will still be caught without any extra work using a handler provided by the framework.

7. Change the code to continue with the asynchronous implementation by replacing the lines with the new code as shown below

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex04 - ReadAsStringAsync*)

```
public async Task<ActionResult> Index()
{
    var client = new HttpClient();
    var response = await client.GetAsync(Url.Action("gallery", "photo", null, Request.Url.Scheme));
    var value = await response.Content.ReadAsStringAsync();
    var result = await JsonConvert.DeserializeObjectAsync<List<Photo>>(value);

    return View(result);
}
```

8. Run the application. You will notice no major changes, but your code will not block a thread from the thread pool making a better usage of the server resources and improving performance.

> **NOTE**
> You can learn more about the new asynchronous programming features in the lab "**Asynchronous Programming in .NET 4.5 with C# and Visual Basic**" included in the Visual Studio Training Kit.

Task 2 - Handling Time-Outs with Cancellation Tokens

Asynchronous action methods that return Task instances can also support time-outs. In this task, you will update the Index method code to handle a time-out scenario using a cancellation token.

1. Go back to Visual Studio and press **SHIFT + F5** to stop debugging.
2. Add the following using statement to the **HomeController.cs** file.

```
using System.Threading;
```

3. Update the Index action to receive a **CancellationToken** argument.

```
public async Task<ActionResult> Index(CancellationToken cancellationToken)
{
    ...
```

4. Update the **GetAsync** call to pass the cancellation token.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex04 - SendAsync with CancellationToken*)

```
public async Task<ActionResult> Index(CancellationToken cancellationToken)
{
    var client = new HttpClient();
    var response = await client.GetAsync(Url.Action("gallery", "photo", null, Request.Url.Scheme),
cancellationToken);
    var value = await response.Content.ReadAsStringAsync();
    var result = await JsonConvert.DeserializeObjectAsync<List<Photo>>(value);

    return View(result);
}
```

5. Decorate the *Index* method with an **AsyncTimeout** attribute set to 500 milliseconds and a **HandleError** attribute configured to handle **TaskCanceledException** by redirecting to a **TimedOut** view.

   (Code Snippet - *ASP.NET MVC 4 Lab - Ex04 - Attributes*)

```
[AsyncTimeout(500)]
[HandleError(ExceptionType = typeof(TimeoutException), View = "TimedOut")]
public async Task<ActionResult> Index(CancellationToken cancellationToken)
{
```

6. Open the **PhotoController** class and update the **Gallery** method to delay the execution 1000 milliseconds (1 second) to simulate a long running task.

```
public ActionResult Gallery()
{
    System.Threading.Thread.Sleep(1000);

    return this.File("~/App_Data/Photos.json", "application/json");
}
```

7. Open the **Web.config** file and enable custom errors by adding the following element.

```
<system.web>
  <customErrors mode="On"></customErrors>
  ...
```

8. Create a new view in **Views\Shared** named **TimedOut** and use the default layout. In the Solution Explorer, right-click the **Views\Shared** folder and select **Add | View**.

Using different views for each mobile device

9. Update the **TimedOut** view content as shown below.

```
@{
    ViewBag.Title = "TimedOut";
    Layout = "~/Views/Shared/_Layout.cshtml";
}

<h2>Timed Out!</h2>
```

10. Run the application and navigate to the root URL. As you have added a **Thread.Sleep** of 1000 milliseconds, you will get a time-out error, generated by the **AsyncTimeout** attribute and catch by the **HandleError** attribute.

Time-out exception handled

> **NOTE**
>
> Additionally, you can deploy this application to Windows Azure Web Sites following Appendix D: Publishing an ASP.NET MVC 4 Application using Web Deploy.

Summary

In this hands-on-lab, you've observed some of the new features resident in ASP.NET MVC 4. The following concepts have been discussed:

- Take advantage of the enhancements to the ASP.NET MVC project templates-including the new mobile application project template
- Use the HTML5 viewport attribute and CSS media queries to improve the display on mobile devices
- Use jQuery Mobile for progressive enhancements and for building touch-optimized web UI
- Create mobile-specific views
- Use the view-switcher component to toggle between mobile and desktop views in the application
- Create asynchronous controllers using task support

Appendix A: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML)

1. Right-click where you want to insert the code snippet.
2. Select **Insert Snippet** followed by **My Code Snippets**.
3. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

Appendix B: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix C: Installing WebMatrix 2 and iPhone Simulator

To run your site in a simulated iPhone device you can use the WebMatrix extension "Electric Mobile Simulator for the iPhone". Also, you can configure the same extension to run the simulator from Visual Studio 2012.

Task 1 - Installing WebMatrix 2

1. Go to [https://go.microsoft.com/?linkid=9809776](https://go.microsoft.com/?linkid=9810169). Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*WebMatrix 2*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install WebMatrix 2

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

Task 2 - Installing the iPhone Simulator Extension

1. Run **WebMatrix** and open any existing Web site or create a new one.

2. Click the **Run** button from the **Home** ribbon and select **Add new**.

Adding new WebMatrix extension

3. Select **iPhone Simulator** and click **Install**.

Browsing WebMatrix extensions

4. In the package details, click **Install** to continue with the extension installation.

iPhone Simulator extension

5. Read and accept the extension EULA.

WebMatrix extension EULA

6. Now, you can run your Web site from WebMatrix using the iPhone Simulator option.

Run using iPhone

Task 3 - Configuring Visual Studio 2012 to run iPhone Simulator

1. Open **Visual Studio 2012** and open any Web site or create a new project.

2. Click the down arrow from the Run button and select **Browse with**.

Browse with

3. In the "Browse With" dialog, click **Add**.

4. In the "Add Program" dialog, use the following values:

   - **Program**: C:\Users*{CurrentUser}*\AppData\Local\Microsoft\WebMatrix\Extensions\20\iPhoneSimulator\ElectricMobileSim\ElectricMobileSim.exe *(update the path accordingly)*

- **Arguments**: "1"
- **Friendly name**: iPhone Simulator

Add program to browse with

5. Click **OK** and close the dialogs.
6. Now you are able to run your Web applications in the iPhone simulator from Visual Studio 2012.

Browse with iPhone Simulator

Appendix D: Publishing an ASP.NET MVC 4 Application using Web Deploy

This appendix will show you how to create a new web site from the Windows Azure Management Portal and publish the application you obtained by following the lab, taking advantage of the Web Deploy publishing feature provided by Windows Azure.

Task 1 - Creating a New Web Site from the Windows Azure Portal

1. Go to the Windows Azure Management Portal and sign in using the Microsoft credentials associated with your subscription.

> **NOTE**
> With Windows Azure you can host 10 ASP.NET Web Sites for free and then scale as your traffic grows. You can sign up here.

Log on to Windows Azure Management Portal

2. Click **New** on the command bar.

Creating a new Web Site

3. Click **Compute | Web Site**. Then select **Quick Create** option. Provide an available URL for the new web site and click **Create Web Site**.

> **NOTE**
>
> A Windows Azure Web Site is the host for a web application running in the cloud that you can control and manage. The Quick Create option allows you to deploy a completed web application to the Windows Azure Web Site from outside the portal. It does not include steps for setting up a database.

Creating a new Web Site using Quick Create

4. Wait until the new **Web Site** is created.

5. Once the Web Site is created click the link under the **URL** column. Check that the new Web Site is working.

Browsing to the new web site

Web site running

6. Go back to the portal and click the name of the web site under the **Name** column to display the management pages.

Opening the Web Site management pages

7. In the **Dashboard** page, under the **quick glance** section, click the **Download publish profile** link.

> **NOTE**
>
> The *publish profile* contains all of the information required to publish a web application to a Windows Azure website for each enabled publication method. The publish profile contains the URLs, user credentials and database strings required to connect to and authenticate against each of the endpoints for which a publication method is enabled. **Microsoft WebMatrix 2**, **Microsoft Visual Studio Express for Web** and **Microsoft Visual Studio 2012** support reading publish profiles to automate configuration of these programs for publishing web applications to Windows Azure websites.

Downloading the Web Site publish profile

8. Download the publish profile file to a known location. Further in this exercise you will see how to use this file to publish a web application to a Windows Azure Web Sites from Visual Studio.

Saving the publish profile file

Task 2 - Configuring the Database Server

If your application makes use of SQL Server databases you will need to create a SQL Database server. If you want to deploy a simple application that does not use SQL Server you might skip this task.

1. You will need a SQL Database server for storing the application database. You can view the SQL Database servers from your subscription in the Windows Azure Management portal at **Sql Databases | Servers | Server's Dashboard**. If you do not have a server created, you can create one using the **Add** button on the command bar. Take note of the **server name and URL, administrator login name and password**, as you will use them in the next tasks. Do not create the database yet, as it will be created in a later stage.

SQL Database Server Dashboard

2. In the next task you will test the database connection from Visual Studio, for that reason you need to include your local IP address in the server's list of **Allowed IP Addresses**. To do that, click **Configure**, select the IP address from **Current Client IP Address** and paste it on the **Start IP Address** and **End IP Address** text

boxes and click the ✔ button.

Adding Client IP Address

3. Once the **Client IP Address** is added to the allowed IP addresses list, click on **Save** to confirm the changes.

Confirm Changes

Task 3 - Publishing an ASP.NET MVC 4 Application using Web Deploy

1. Go back to the ASP.NET MVC 4 solution. In the **Solution Explorer**, right-click the web site project and select **Publish**.

Publishing the web site

2. Import the publish profile you saved in the first task.

Importing publish profile

3. Click **Validate Connection**. Once Validation is complete click **Next**.

> **NOTE**
>
> Validation is complete once you see a green checkmark appear next to the Validate Connection button.

Validating connection

4. In the **Settings** page, under the **Databases** section, click the button next to your database connection's textbox (i.e. **DefaultConnection**).

Web deploy configuration

5. Configure the database connection as follows:

   - In the **Server name** type your SQL Database server URL using the *tcp:* prefix.
   - In **User name** type your server administrator login name.
   - In **Password** type your server administrator login password.
   - Type a new database name, for example: *MVC4SampleDB*.

Configuring destination connection string

6. Then click **OK**. When prompted to create the database click **Yes**.

Creating the database

7. The connection string you will use to connect to SQL Database in Windows Azure is shown within Default Connection textbox. Then click **Next**.

Connection string pointing to SQL Database

8. In the **Preview** page, click **Publish**.

Publishing the web application

9. Once the publishing process finishes, your default browser will open the published web site.

Application published to Windows Azure

ASP.NET MVC 4 Fundamentals

2/20/2020 • 48 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

This Hands-On Lab is based on MVC (Model View Controller) Music Store, a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio. Throughout the lab you will learn the simplicity, yet power of using these technologies together. You will start with a simple application and will build it until you have a fully functional ASP.NET MVC 4 Web Application.

This Lab works with ASP.NET MVC 4.

If you wish to explore the ASP.NET MVC 3 version of the tutorial application, you can find it in MVC-Music-Store.

This Hands-On Lab assumes that the developer has experience in Web development technologies, such as HTML and JavaScript.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Fundamentals.

The Music Store application

The Music Store web application that will be built throughout this Lab comprises three main parts: shopping, checkout, and administration. Visitors will be able to browse albums by genre, add albums to their cart, review their selection and finally proceed to checkout to login and complete the order. Additionally, store administrators will be able to manage the available albums as well as their main properties.

Music Store screens

ASP.NET MVC 4 Essentials

Music Store application will be built using **Model View Controller (MVC)**, an architectural pattern that separates an application into three main components:

- **Models**: Model objects are the parts of the application that implement the domain logic. Often, model objects also retrieve and store model state in a database.
- **Views:** Views are the components that display the application's user interface (UI). Typically, this UI is created from the model data. An example would be the edit view of Albums that displays text boxes and a drop-down list based on the current state of an Album object.
- **Controllers:** Controllers are the components that handle user interaction, manipulate the model, and ultimately select a view to render the UI. In an MVC application, the view only displays information; the controller handles and responds to user input and interaction.

The MVC pattern helps you to create applications that separate the different aspects of the application (input logic, business logic, and UI logic), while providing a loose coupling between these elements. This separation helps you manage complexity when you build an application, as it allows you to focus on one aspect of the implementation at a time. In addition, the MVC pattern makes it easy to test applications, also encouraging the use of test-driven development (TDD) for creating applications.

The **ASP.NET MVC** framework provides an alternative to the ASP.NET Web Forms pattern for creating ASP.NET MVC-based Web applications. The **ASP.NET MVC** framework is a lightweight, highly testable presentation framework that (as with Web-forms-based applications) is integrated with existing ASP.NET features, such as master pages and membership-based authentication so you get all the power of the core .NET framework. This is useful if you are already familiar with ASP.NET Web Forms because all the libraries that you already use are available in ASP.NET MVC 4 as well.

In addition, the loose coupling between the three main components of an MVC application also promotes parallel development. For instance, one developer can work on the view, a second developer can work on the controller logic, and a third developer can focus on the business logic in the model.

Objectives

In this Hands-On Lab, you will learn how to:

- Create an ASP.NET MVC application from scratch based on the Music Store Application tutorial
- Add Controllers to handle URLs to the Home page of the site and for browsing its main functionality
- Add a View to customize the content displayed along with its style
- Add Model classes to contain and manage data and domain logic
- Use View Model pattern to pass information from controller actions to the view templates
- Explore the ASP.NET MVC 4 new template for internet applications

Prerequisites

You must have the following items to complete this lab:

- Visual Studio 2012 Express for Web (read Appendix A for instructions on how to install it)

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run **.\Source\Setup\CodeSnippets.vsi** file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix C: Using Code Snippets".

Exercises

This Hands-On Lab is comprised by the following exercises:

1. Exercise 1: Creating MusicStore ASP.NET MVC Web Application Project
2. Exercise 2: Creating a Controller
3. Exercise 3: Passing parameters to a Controller
4. Exercise 4: Creating a View
5. Exercise 5: Creating a View Model
6. Exercise 6: Using parameters in View
7. Exercise 7: A lap around ASP.NET MVC 4 New Template

> **NOTE**
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **60 minutes**.

Exercise 1: Creating MusicStore ASP.NET MVC Web Application Project

In this exercise, you will learn how to create an ASP.NET MVC application in Visual Studio 2012 Express for Web as well as its main folder organization. Additionally, you will learn how to add a new Controller and make it display a simple string in the application's home page.

Task 1 - Creating the ASP.NET MVC Web Application Project

1. In this task, you will create an empty ASP.NET MVC application project using the MVC Visual Studio template. Start **VS Express for Web**.
2. On the **File** menu, click **New Project**.
3. In the **New Project** dialog box select the **ASP.NET MVC 4 Web Application** project type, located under **Visual C#, Web** template list.
4. Change the **Name** to *MvcMusicStore*.
5. Set the location of the solution inside a new **Begin** folder in this Exercise's Source folder, for example **[YOUR-HOL-PATH]\Source\Ex01-CreatingMusicStoreProject\Begin**. Click **OK**.

Create New Project Dialog Box

6. In the **New ASP.NET MVC 4 Project** dialog box select the **Basic** template and make sure that the **View engine** selected is **Razor**. Click **OK**.

New ASP.NET MVC 4 Project Dialog Box

Task 2 - Exploring the Solution Structure

The ASP.NET MVC framework includes a Visual Studio project template that helps you create Web applications supporting the MVC pattern. This template creates a new ASP.NET MVC Web application with the required folders, item templates, and configuration-file entries.

In this task, you will examine the solution structure to understand the elements that are involved and their relationships. The following folders are included in all the ASP.NET MVC application because the ASP.NET MVC framework by default uses a "convention over configuration" approach, and makes some default assumptions based on folder naming conventions.

1. Once the project is created, review the folder structure that has been created in the Solution Explorer on the right side:

ASP.NET MVC Folder structure in Solution Explorer

a. **Controllers**. This folder will contain the controller classes. In an MVC based application, controllers are responsible for handling end user interaction, manipulating the model, and ultimately choosing a view to render the UI.

> **NOTE**
>
> The MVC framework requires the names of all controllers to end with "Controller"-for example, HomeController, LoginController, or ProductController.

b. **Models**. This folder is provided for classes that represent the application model for the MVC Web application. This usually includes code that defines objects and the logic for interacting with the data store. Typically, the actual model objects will be in separate class libraries. However, when you create a new application, you might include classes and then move them into separate class libraries at a later point in the development cycle.

c. **Views**. This folder is the recommended location for views, the components responsible for displaying the application's user interface. Views use .aspx, .ascx, .cshtml and .master files, in addition to any other files that are related to rendering views. Views folder contains a folder for each controller; the folder is named with the controller-name prefix. For example, if you have a controller named **HomeController**, the Views folder will contain a folder named Home. By default, when the ASP.NET MVC framework loads a view, it looks for an .aspx file with the requested view name in the Views\controllerName folder (**Views[ControllerName][Action].aspx**) or (**Views[ControllerName][Action].cshtml**) for Razor Views.

> **NOTE**
>
> In addition to the folders listed previously, an MVC Web application uses the **Global.asax** file to set global URL routing defaults, and it uses the **Web.config** file to configure the application.

Task 3 - Adding a HomeController

In ASP.NET applications that do not use the MVC framework, user interaction is organized around pages, and around raising and handling events from those pages. In contrast, user interaction with ASP.NET MVC applications is organized around controllers and their action methods.

On the other hand, ASP.NET MVC framework maps URLs to classes that are referred to as controllers. Controllers process incoming requests, handle user input and interactions, execute appropriate application logic and determine the response to send back to the client (display HTML, download a file, redirect to a different URL, etc.). In the case of displaying HTML, a controller class typically calls a separate view component to generate the HTML markup for the request. In an MVC application, the view only displays information; the controller handles and responds to user input and interaction.

In this task, you will add a Controller class that will handle URLs to the Home page of the Music Store site.

1. Right-click **Controllers** folder within the Solution Explorer, select **Add** and then **Controller** command:

Add Controller Command

2. The **Add Controller** dialog appears. Name the controller *HomeController* and press **Add**.

Add Controller Dialog

3. The file **HomeController.cs** is created in the **Controllers** folder. In order to have the **HomeController** return a string on its Index action, replace the **Index** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex1 HomeController Index*)

```
public string Index()
{
    return "Hello from Home";
}
```

Task 4 - Running the Application

In this task, you will try out the Application in a web browser.

1. Press **F5** to run the Application. The project is compiled and the local IIS Web Server starts. The local IIS Web Server will automatically open a web browser pointing to the URL of the Web server.

Application running in a web browser

> **NOTE**
> The local IIS Web Server will run the website on a random free port number. In the figure above, the site is running at `http://localhost:50103/`, so it's using port 50103. Your port number may vary.

2. Close the browser.

Exercise 2: Creating a Controller

In this exercise, you will learn how to update the controller to implement simple functionality of the Music Store application. That controller will define action methods to handle each of the following specific requests:

- A listing page of the music genres in the Music Store
- A browse page that lists all of the music albums for a particular genre
- A details page that shows information about a specific music album

For the scope of this exercise, those actions will simply return a string by now.

Task 1 - Adding a New StoreController Class

In this task, you will add a new Controller.

1. If not already open, start **VS Express for Web 2012**.

2. In the **File** menu, choose **Open Project**. In the Open Project dialog, browse to **Source\Ex02-CreatingAController\Begin**, select **Begin.sln** and click **Open**. Alternatively, you may continue with the solution that you obtained after completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Add the new controller. To do this, right-click the **Controllers** folder within the Solution Explorer, select **Add** and then the **Controller** command. Change the **Controller Name** to *StoreController*, and click **Add**.

Add Controller Dialog

Task 2 - Modifying the StoreController's Actions

In this task, you will modify the Controller methods that are called **actions**. Actions are responsible for handling URL requests and determining the content that should be sent back to the browser or user that invoked the URL.

1. The **StoreController** class already has an **Index** method. You will use it later in this Lab to implement the page that lists all genres of the music store. For now, just replace the **Index** method with the following code that returns a string "Hello from Store.Index()":

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex2 StoreController Index*)

```
public string Index()
{
  return "Hello from Store.Index()";
}
```

2. Add **Browse** and **Details** methods. To do this, add the following code to the **StoreController**:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex2 StoreController BrowseAndDetails*)

```
// GET: /Store/Browse
public string Browse()
{
  return "Hello from Store.Browse()";
}

// GET: /Store/Details
public string Details()
{
  return "Hello from Store.Details()";
}
```

Task 3 - Running the Application

In this task, you will try out the Application in a web browser.

1. Press **F5** to run the Application.

2. The project starts in the **Home** page. Change the URL to verify each action's implementation.

   a. **/Store**. You will see **"Hello from Store.Index()"**.

b. **/Store/Browse**. You will see **"Hello from Store.Browse()"**.

c. **/Store/Details**. You will see **"Hello from Store.Details()"**.

Browsing /Store/Browse

3. Close the browser.

Exercise 3: Passing parameters to a Controller

Until now, you have been returning constant strings from the Controllers. In this exercise you will learn how to pass parameters to a Controller using the URL and querystring, and then making the method actions respond with text to the browser.

Task 1 - Adding Genre Parameter to StoreController

In this task, you will use the **querystring** to send parameters to the **Browse** action method in the **StoreController**.

1. If not already open, start **VS Express for Web**.

2. In the **File** menu, choose **Open Project**. In the Open Project dialog, browse to **Source\Ex03-PassingParametersToAController\Begin**, select **Begin.sln** and click **Open**. Alternatively, you may continue with the solution that you obtained after completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Open **StoreController** class. To do this, in the **Solution Explorer**, expand the **Controllers** folder and double-click **StoreController.cs**.

4. Change the **Browse** method, adding a string parameter to request for a specific genre. ASP.NET MVC will automatically pass any querystring or form post parameters named **genre** to this action method when invoked. To do this, replace the **Browse** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex3 StoreController BrowseMethod*)

```
// GET: /Store/Browse?genre=Disco
public string Browse(string genre)
{
  string message = HttpUtility.HtmlEncode("Store.Browse, Genre = " + genre);

  return message;
}
```

> **NOTE**
>
> You are using the **HttpUtility.HtmlEncode** utility method to prevents users from injecting Javascript into the View with a link like **/Store/Browse?Genre=<script>window.location='http://hackersite.com'</script>**.
>
> For further explanation, please visit this msdn article.

Task 2 - Running the Application

In this task, you will try out the Application in a web browser and use the **genre** parameter.

1. Press **F5** to run the Application.

2. The project starts in the **Home** page. Change the URL to */Store/Browse?Genre=Disco* to verify that the action receives the genre parameter.

   Browsing /Store/Browse?Genre=Disco

3. Close the browser.

Task 3 - Adding an Id Parameter Embedded in the URL

In this task, you will use the **URL** to pass an **Id** parameter to the **Details** action method of the **StoreController**. ASP.NET MVC's default routing convention is to treat the segment of a URL after the action method name as a parameter named **Id**. If your action method has parameter named Id, then ASP.NET MVC will automatically pass

the URL segment to you as a parameter. In the URL **Store/Details/5**, **Id** will be interpreted as **5**.

1. Change the **Details** method of the **StoreController**, adding an **int** parameter called **id**. To do this, replace the **Details** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex3 StoreController DetailsMethod*)

```
// GET: /Store/Details/5
public string Details(int id)
{
  string message = "Store.Details, ID = " + id;

  return message;
}
```

Task 4 - Running the Application

In this task, you will try out the Application in a web browser and use the **Id** parameter.

1. Press **F5** to run the Application.

2. The project starts in the **Home** page. Change the URL to */Store/Details/5* to verify that the action receives the id parameter.

Browsing /Store/Details/5

Exercise 4: Creating a View

So far you have been returning strings from controller actions. Although that is a useful way of understanding how controllers work, it is not how your real Web applications are built. Views are components that provide a better approach for generating HTML back to the browser with the use of template files.

In this exercise you will learn how to add a layout master page to setup a template for common HTML content, a StyleSheet to enhance the look and feel of the site and finally a View template to enable HomeController to return HTML.

Task 1 - Modifying the file _layout.cshtml

The file **~/Views/Shared/_layout.cshtml** allows you to setup a template for common HTML to use across the entire website. In this task you will add a layout master page with a common header with links to the Home page and Store area.

1. If not already open, start **VS Express for Web**.
2. In the **File** menu, choose **Open Project**. In the Open Project dialog, browse to **Source\Ex04-CreatingAView\Begin**, select **Begin.sln** and click **Open**. Alternatively, you may continue with the solution that you obtained after completing the previous exercise.
   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.
   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.
   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. The file **_layout.cshtml** contains the HTML container layout for all pages on the site. It includes the **<html>** element for the HTML response, as well as the **<head>** and **<body>** elements. **@RenderBody()** within the HTML body identify regions that view templates will be able to fill in with dynamic content. (C#)

```
<!DOCTYPE html>
<html>
<head>
     <meta charset="utf-8" />
     <meta name="viewport" content="width=device-width" />
     <title>@ViewBag.Title</title>
     @Styles.Render("~/Content/css")
     @Scripts.Render("~/bundles/modernizr")
</head>
<body>
     @RenderBody()

     @Scripts.Render("~/bundles/jquery")
     @RenderSection("scripts", required: false)
</body>
</html>
```

4. Add a common header with links to the Home page and Store area on all pages in the site. In order to do that, add the following code below <body> statement. (C#)

```
<!DOCTYPE html>
<html>
<head>
     <meta charset="utf-8" />
     <meta name="viewport" content="width=device-width" />
     <title>@ViewBag.Title</title>
     @Styles.Render("~/Content/css")
     @Scripts.Render("~/bundles/modernizr")
</head>
<body>
     <header>
          <div class="content-wrapper">
                <div class="float-left">
                     <p class="site-title">@Html.ActionLink("ASP.NET MVC Music Store", "Index", "Home")
</p>
                </div>
                <div class="float-right">
                     <nav>
                          <ul id="menu">
                                <li>@Html.ActionLink("Home", "Index", "Home")</li>
                                <li>@Html.ActionLink("Store", "Index", "Store")</li>
                          </ul>
                     </nav>
                </div>
          </div>
     </header>
     @RenderBody()

     @Scripts.Render("~/bundles/jquery")
     @RenderSection("scripts", required: false)
</body>
</html>
```

5. Include a div to render the body section of each page. Replace **@RenderBody()** with the following highlighted code: (C#)

```
...
<body>
     <header>
          <div class="content-wrapper">
                <div class="float-left">
                     <p class="site-title">@Html.ActionLink("ASP.NET MVC Music Store", "Index", "Home")
</p>
                </div>
                <div class="float-right">
                     <nav>
                          <ul id="menu">
                                <li>@Html.ActionLink("Home", "Index", "Home")</li>
                                <li>@Html.ActionLink("Store", "Index", "Store")</li>
                          </ul>
                     </nav>
                </div>
          </div>
     </header>
     <div id="body">
          @RenderSection("featured", required: false)
          <section class="content-wrapper main-content clear-fix">
                @RenderBody()
          </section>
     </div>
     ...
</body>
</html>
```

> **NOTE**
>
> Did you know? Visual Studio 2012 has snippets that make it easy to add commonly used code in HTML, code files and more! Try it out by typing ** ** and pressing **TAB** twice to insert a complete **div** tag.

Task 2 - Adding CSS Stylesheet

The empty project template includes a very streamlined CSS file which just includes styles used to display basic forms and validation messages. You will use additional CSS and images (potentially provided by a designer) in order to enhance the look and feel of the site.

In this task, you will add a CSS stylesheet to define the styles of the site.

1. The CSS file and images are included in the **Source\Assets\Content** folder of this Lab. In order to add them to the application, drag their content from a **Windows Explorer** window into the **Solution Explorer** in Visual Studio Express for Web, as shown below:

Dragging style contents

2. A warning dialog will appear, asking for confirmation to replace **Site.css** file and some existing images. Check **Apply to all items** and click **Yes**.

Task 3 - Adding a View Template

In this task, you will add a View template to generate the HTML response that will use the layout master page and CSS added in this exercise.

1. To use a View template when browsing the site's home page, you will first need to indicate that instead of returning a string, the **HomeController Index** method will return a **View**. Open **HomeController** class and change its **Index** method to return an **ActionResult**, and have it return **View()**.

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex4 HomeController Index*)

```
public class HomeController : Controller
{
    //
    // GET: /Home/

    public ActionResult Index()
    {
        return this.View();
    }
}
```

2. Now, you need to add an appropriate View template. To do this, **right-click** inside the **Index** action method and select **Add View**. This will bring up the **Add View** dialog.

Adding a View from within the Index method

3. The **Add View** Dialog will appear to generate a View template file. By default, this dialog pre-populates the name of the View template so that it matches the action method that will use it. Because you used the **Add View** context menu within the **Index** action method within the HomeController, the **Add View** dialog has Index as the default view name. Click **Add**.

Add View Dialog

4. Visual Studio generates an **Index.cshtml** view template inside the **Views\Home** folder and then opens it.

Home Index view created

> **NOTE**
>
> name and location of the **Index.cshtml** file is relevant and follows the default ASP.NET MVC naming conventions.
>
> The folder \Views*Home* matches the controller name (**Home** Controller). The View template name (**Index**), matches the controller action method which will be displaying the View.
>
> This way, ASP.NET MVC avoids having to explicitly specify the name or location of a View template when using this naming convention to return a View.

5. The generated View template is based on the **_layout.cshtml** template earlier defined. Update the ViewBag.Title property to **Home**, and change the main content to **This is the Home Page**, as shown in the code below:

```
@{
    ViewBag.Title = "Home";
}

<h2>This is the Home Page</h2>
```

6. Select **MvcMusicStore** project in the Solution Explorer and Press **F5** to run the Application.

Task 4: Verification

In order to verify that you have correctly performed all the steps in the previous exercise, proceed as follows:

With the application opened in a browser, you should note that:

1. The HomeController's Index action method found and displayed the **\Views\Home\Index.cshtml** View template, even though the code called **return View()**, because the View template followed the standard

naming convention.

2. The Home Page displays the welcome message defined within the **\Views\Home\Index.cshtml** view template.

3. The Home Page is using the **_layout.cshtml** template, and so the welcome message is contained within the standard site HTML layout.

Home Index View using the defined LayoutPage and style

Exercise 5: Creating a View Model

So far, you made your Views display hardcoded HTML, but, in order to create dynamic web applications, the View template should receive information from the Controller. One common technique to be used for that purpose is the **ViewModel** pattern, which allows a Controller to package up all the information needed to generate the appropriate HTML response.

In this exercise, you will learn how to create a ViewModel class and add the required properties: the number of genres in the store and a list of those genres. You will also update the StoreController to use the created ViewModel, and finally, you will create a new View template that will display the mentioned properties in the page.

Task 1 - Creating a ViewModel Class

In this task, you will create a ViewModel class that will implement the Store genre listing scenario.

1. If not already open, start **VS Express for Web**.

2. In the **File** menu, choose **Open Project**. In the Open Project dialog, browse to **Source\Ex05-CreatingAViewModel\Begin**, select **Begin.sln** and click **Open**. Alternatively, you may continue with the solution that you obtained after completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Create a **ViewModels** folder to hold the ViewModel. To do this, right-click the top-level **MvcMusicStore** project, select **Add** and then **New Folder**.

Adding a new folder

4. Name the folder *ViewModels*.

ViewModels folder in Solution Explorer

5. Create a **ViewModel** class. To do this, right-click on the **ViewModels** folder recently created, select **Add** and then **New Item**. Under **Code**, choose the **Class** item and name the file *StoreIndexViewModel.cs*, then click **Add**.

Adding a new Class

Creating StoreIndexViewModel class

Task 2 - Adding Properties to the ViewModel class

There are two parameters to be passed from the StoreController to the View template in order to generate the expected HTML response: the number of genres in the store and a list of those genres.

In this task, you will add those 2 properties to the **StoreIndexViewModel** class: **NumberOfGenres** (an integer) and **Genres** (a list of strings).

1. Add **NumberOfGenres** and **Genres** properties to the **StoreIndexViewModel** class. To do this, add the following 2 lines to the class definition:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex5 StoreIndexViewModel properties*)

```
public class StoreIndexViewModel
{
    public int NumberOfGenres { get; set; }

    public List<string> Genres { get; set; }
}
```

> **NOTE**
>
> The **{ get; set; }** notation makes use of C#'s auto-implemented properties feature. It provides the benefits of a property without requiring us to declare a backing field.

Task 3 - Updating StoreController to use the StoreIndexViewModel

The **StoreIndexViewModel** class encapsulates the information needed to pass from **StoreController**'s **Index** method to a View template in order to generate a response.

In this task, you will update the **StoreController** to use the **StoreIndexViewModel**.

1. Open **StoreController** class.

Opening StoreController class

2. In order to use the **StoreIndexViewModel** class from the **StoreController**, add the following namespace at the top of the **StoreController** code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex5 StoreIndexViewModel using ViewModels*)

```
using MvcMusicStore.ViewModels;
```

3. Change the **StoreController**'s **Index** action method so that it creates and populates a **StoreIndexViewModel** object and then passes it off to a View template to generate an HTML response with it.

> **NOTE**
>
> In Lab "ASP.NET MVC Models and Data Access" you will write code that retrieves the list of store genres from a database. In the following code, you will create a **List** of dummy data genres that will populate the **StoreIndexViewModel**.
>
> After creating and setting up the **StoreIndexViewModel** object, it will be passed as an argument to the **View** method. This indicates that the View template will use that object to generate an HTML response with it.

4. Replace the **Index** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex5 StoreController Index method*)

```
public ActionResult Index()
{
    // Create a list of genres
    var genres = new List<string> {"Rock", "Jazz", "Country", "Pop", "Disco"};

    // Create our view model
    var viewModel = new StoreIndexViewModel {
        NumberOfGenres = genres.Count(),
        Genres = genres
    };

    return this.View(viewModel);
}
```

NOTE

If you're unfamiliar with C#, you may assume that using **var** means that the **viewModel** variable is late-bound. That's not correct - the C# compiler is using type-inference based on what you assign to the variable to determine that **viewModel** is of type **StoreIndexViewModel**. Also, by compiling the local **viewModel** variable as a **StoreIndexViewModel** type you get compile-time checking and Visual Studio code-editor support.

Task 4 - Creating a View Template that Uses StoreIndexViewModel

In this task, you will create a View template that will use a StoreIndexViewModel object passed from the Controller to display a list of genres.

1. Before creating the new View template, let's build the project so that the **Add View Dialog** knows about the **StoreIndexViewModel** class. Build the project by selecting the **Build** menu item and then **Build MvcMusicStore**.

Building the project

2. Create a new View template. To do that, right-click inside the **Index** method and select **Add View**.

Adding a View

3. Because the **Add View Dialog** was invoked from the **StoreController**, it will add the View template by default in a **\Views\Store\Index.cshtml** file. Check the **Create a strongly-typed-view** checkbox and then select **StoreIndexViewModel** as the **Model class**. Also, make sure that the View engine selected is **Razor**. Click **Add**.

Add View Dialog

The **\Views\Store\Index.cshtml** View template file is created and opened. Based on the information provided to the **Add View** dialog in the last step, the View template will expect a **StoreIndexViewModel** instance as the data to use to generate an HTML response. You will notice that the template inherits a `ViewPage<musicstore.viewmodels.storeindexviewmodel>` in C#.

Task 5 - Updating the View Template

In this task, you will update the View template created in the last task to retrieve the number of genres and their names within the page.

> **NOTE**
>
> You will use @ syntax (often referred to as "code nuggets") to execute code within the View template.

1. In the **Index.cshtml** file, within the **Store** folder, replace its code with the following:

```
@model MvcMusicStore.ViewModels.StoreIndexViewModel

@{
    ViewBag.Title = "Browse Genres";
}

<h2>Browse Genres</h2>

<p>Select from @Model.NumberOfGenres genres</p>
```

```
> [!NOTE]
> As soon as you finish typing the period after the word **Model**, Visual Studio's Intellisense will show a
list of possible properties and methods to choose from.
>
> ![](aspnet-mvc-4-fundamentals/_static/image25.png)
>
> *Getting Model properties and methods with Visual Studio's IntelliSense*
>
> The **Model** property references the **StoreIndexViewModel** object that the Controller passed to the View
template. This means that you can access all of the data passed from the Controller to the View template via
the **Model** property, and format it into an appropriate HTML response within the View template.
>
> You can just select the **NumberOfGenres** property from the Intellisense list rather than typing it in and
then it will auto-complete it by pressing the **tab key**.
```

2. Loop over the genre list in **StoreIndexViewModel** and create an HTML **<ul>** list using a **foreach** loop. (C#)

```
@model MvcMusicStore.ViewModels.StoreIndexViewModel

@{
    ViewBag.Title = "Browse Genres";
}

<h2>Browse Genres</h2>

<p>Select from @Model.NumberOfGenres genres</p>

<ul>
@foreach (string genreName in Model.Genres)
{
    <li>
        @genreName
    </li>
}
</ul>
```

3. Press **F5** to run the Application and browse **/Store**. You will see the list of genres passed in the **StoreIndexViewModel** object from the **StoreController** to the View template.

View displaying a list of genres

4. Close the browser.

Exercise 6: Using Parameters in View

In Exercise 3 you learned how to pass parameters to the Controller. In this exercise, you will learn how to use those parameters in the View template. For that purpose, you will be introduced first to Model classes that will help you to manage your data and domain logic. Additionally, you will learn how to create links to pages inside the ASP.NET MVC application without worrying of things like URL paths encoding.

Task 1 - Adding Model Classes

Unlike ViewModels, which are created just to pass information from the Controller to the View, Model classes are built to contain and manage data and domain logic. In this task you will add two model classes to represent these concepts: **Genre** and **Album**.

1. If not already open, start **VS Express for Web**

2. In the **File** menu, choose **Open Project**. In the Open Project dialog, browse to **Source\Ex06-UsingParametersInView\Begin**, select **Begin.sln** and click **Open**. Alternatively, you may continue with the solution that you obtained after completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

3. Add a **Genre** Model class. To do this, right-click the **Models** folder in the **Solution Explorer**, select **Add** and then the **New Item** option. Under **Code**, choose the **Class** item and name the file *Genre.cs*, then click **Add**.

Adding a new item

Add Genre Model Class

4. Add a **Name** property to the Genre class. To do this, add the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 Genre*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;

namespace MvcMusicStore.Models
{
    public class Genre
    {
        public string Name { get; set; }
    }
}
```

5. Following the same procedure as before, add an **Album** class. To do this, right-click the **Models** folder in the **Solution Explorer**, select **Add** and then the **New Item** option. Under **Code**, choose the **Class** item and name the file *Album.cs*, then click **Add**.

6. Add two properties to the Album class: **Genre** and **Title**. To do this, add the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 Album*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;

namespace MvcMusicStore.Models
{
    public class Album
    {
        public string Title { get; set; }

        public Genre Genre { get; set; }
    }
}
```

Task 2 - Adding a StoreBrowseViewModel

A **StoreBrowseViewModel** will be used in this task to show the Albums that match a selected Genre. In this task, you will create this class and then add two properties to handle the **Genre** and its **Album**'s List.

1. Add a **StoreBrowseViewModel** class. To do this, right-click the **ViewModels** folder in the **Solution Explorer**, select **Add** and then the **New Item** option. Under **Code**, choose the **Class** item and name the file *StoreBrowseViewModel.cs*, then click **Add**.

2. Add a reference to the Models in **StoreBrowseViewModel** class. To do this, add the following using namespace:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 UsingModel*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using MvcMusicStore.Models;

namespace MvcMusicStore.ViewModels
{
    public class StoreBrowseViewModel
    {
    }
}
```

3. Add two properties to **StoreBrowseViewModel** class: **Genre** and **Albums**. To do this, add the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 ModelProperties*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using MvcMusicStore.Models;

namespace MvcMusicStore.ViewModels
{
    public class StoreBrowseViewModel
    {
        public Genre Genre { get; set; }

        public List<Album> Albums { get; set; }
    }
}
```

NOTE

What is **List<Album>** ?: This definition is using the **List<T>** type, where **T** constrains the type to which elements of this **List** belong to, in this case **Album** (or any of its descendants).

This ability to design classes and methods that defer the specification of one or more types until the class or method is declared and instantiated by client code is a feature of the C# language called **Generics**.

List<T> is the generic equivalent of the **ArrayList** type and is available in the **System.Collections.Generic** namespace. One of the benefits of using **generics** is that since the type is specified, you do not need to take care of type checking operations such as casting the elements into **Album** as you would do with an **ArrayList**.

Task 3 - Using the New ViewModel in the StoreController

In this task, you will modify the **StoreController**'s **Browse** and **Details** action methods to use the new **StoreBrowseViewModel**.

1. Add a reference to the Models folder in **StoreController** class. To do this, expand the **Controllers** folder in the **Solution Explorer** and open the **StoreController** class. Then add the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 UsingModelInController*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.ViewModels;
using MvcMusicStore.Models;
```

2. Replace the **Browse** action method to use the **StoreViewBrowseController** class. You will create a Genre and two new Albums objects with dummy data (in the next Hands-on Lab you will consume real data from a database). To do this, replace the **Browse** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 BrowseMethod*)

```
//
// GET: /Store/Browse?genre=Disco

public ActionResult Browse(string genre)
{
    var genreModel = new Genre()
    {
        Name = genre
    };

    var albums = new List<Album>()
    {
        new Album() { Title = genre + " Album 1" },
        new Album() { Title = genre + " Album 2" }
    };

    var viewModel = new StoreBrowseViewModel()
    {
        Genre = genreModel,
        Albums = albums
    };

    return this.View(viewModel);
}
```

3. Replace the **Details** action method to use the **StoreViewBrowseController** class. You will create a new **Album** object to be returned to the **View**. To do this, replace the **Details** method with the following code:

   (Code Snippet - *ASP.NET MVC 4 Fundamentals - Ex6 DetailsMethod*)

```
//
// GET: /Store/Details/5

public ActionResult Details(int id)
{
  var album = new Album { Title = "Sample Album" };

  return this.View(album);
}
```

Task 4 - Adding a Browse View Template

In this task, you will add a **Browse** View to show the Albums found for a specific Genre.

1. Before creating the new View template, you should build the project so that the **Add View** Dialog knows about the **ViewModel** class to use. Build the project by selecting the **Build** menu item and then **Build MvcMusicStore**.

2. Add a **Browse** View. To do this, right-click in the **Browse** action method of the **StoreController** and click **Add View**.

3. In the **Add View** dialog box, verify that the View Name is **Browse**. Check the **Create a strongly-typed view** checkbox and select **StoreBrowseViewModel** from the **Model class** dropdown. Leave the other fields with their default value. Then click **Add**.

Adding a Browse View

4. Modify the **Browse.cshtml** to display the Genre's information, accessing the **StoreBrowseViewModel** object that is passed to the view template. To do this, replace the content with the following: (C#)

```
@model MvcMusicStore.ViewModels.StoreBrowseViewModel

@{
    ViewBag.Title = "Browse Albums";
}

<h2>Browsing Genre: @Model.Genre.Name</h2>

<ul>
    @foreach (var album in Model.Albums)
    {
        <li>@album.Title</li>
    }
</ul>
```

Task 5 - Running the Application

In this task, you will test that the **Browse** method retrieves Albums from the **Browse** method action.

1. Press **F5** to run the Application.
2. The project starts in the Home page. Change the URL to **/Store/Browse?Genre=Disco** to verify that the action returns two Albums.

Browsing Store Disco Albums

Task 6 - Displaying information About a Specific Album

In this task, you will implement the **Store/Details** view to display information about a specific album. In this Hands-on Lab, everything you will display about the album is already contained in the **View** template. So, instead of creating a **StoreDetailsViewModel** class, you will use the current **StoreBrowseViewModel** template passing the Album to it.

1. Close the browser if needed, to return to the Visual Studio window. Add a new **Details** view for the **StoreController**'s **Details** action method. To do this, right-click the **Details** method in the **StoreController** class and click **Add View**.
2. In the **Add View** dialog, verify that the **View Name** is **Details**. Check the **Create a strongly-typed view** checkbox and select **Album** from the **Model class** drop-down. Leave the other fields with their default value. Then click **Add**. This will create and open a **\Views\Store\Details.cshtml** file.

Adding a Details View

3. Modify the **Details.cshtml** file to display the Album's information, accessing the **Album** object that is passed to the view template. To do this, replace the content with the following: (C#)

```
@model MvcMusicStore.Models.Album

@{
    ViewBag.Title = "Details";
}

<h2>Album: @Model.Title</h2>
```

Task 7 - Running the Application

In this task, you will test that the **Details** View retrieves Album's information from the **Details action** method.

1. Press **F5** to run the Application.

2. The project starts in the **Home** page. Change the URL to **/Store/Details/5** to verify the album's information.

Browsing Album's Detail

Task 8 - Adding Links Between Pages

In this task, you will add a link in the Store View to have a link in every Genre name to the appropriate **/Store/Browse** URL. This way, when you click on a Genre, for instance **Disco**, it will navigate to **/Store/Browse?genre=Disco** URL.

1. Close the browser if needed, to return to the Visual Studio window. Update the **Index** page to add a link to the **Browse** page. To do this, in the **Solution Explorer** expand the **Views** folder, then the **Store** folder and double-click the **Index.cshtml** page.

2. Add a link to the Browse view indicating the genre selected. To do this, replace the following highlighted code within the **<li>** tags: (C#)

```
@model MvcMusicStore.ViewModels.StoreIndexViewModel

@{
    ViewBag.Title = "Browse Genres";
}

<h2>Browse Genres</h2>

<p> Select from @Model.NumberOfGenres genres</p>

<ul>
    @foreach (string genreName in Model.Genres) {
        <li>
            @Html.ActionLink(genreName, "Browse", new { genre = genreName }, null)
        </li>
        }
</ul>
```

NOTE

another approach would be linking directly to the page, with a code like the following:

@genreName

Although this approach works, it depends on a hardcoded string. If you later rename the Controller, you will have to change this instruction manually. A better alternative is to use an **HTML Helper** method. ASP.NET MVC includes an HTML Helper method which is available for such tasks. The **Html.ActionLink()** helper method makes it easy to build HTML **<a>** links, making sure URL paths are properly URL encoded.

Html.ActionLink has several overloads. In this exercise you will use one that takes three parameters:

1. Link text, which will display the Genre name
2. Controller action name (**Browse**)
3. Route parameter values, specifying both the name (**Genre**) and the value (**Genre name**)

Task 9 - Running the Application

In this task, you will test that each Genre is displayed with a link to the appropriate **/Store/Browse** URL.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/Store** to verify that each Genre links to the appropriate **/Store/Browse** URL.

Browsing Genres with links to Browse page

Task 10 - Using Dynamic ViewModel Collection to Pass Values

In this task, you will learn a simple and powerful method to pass values between the Controller and the View without making any changes in the Model. ASP.NET MVC 4 provides the collection "ViewModel", which can be assigned to any dynamic value and accessed inside controllers and views as well.

You will now use the ViewBag dynamic collection to pass a list of "**Starred genres**" from the controller to the view. The Store Index view will access to **ViewModel** and display the information.

1. Close the browser if needed, to return to the Visual Studio window. Open **StoreController.cs** and modify **Index** method to create a list of starred genres into ViewModel collection :

```
public ActionResult Index()
{
    // Create list of genres
    var genres = new List<string> { "Rock", "Jazz", "Country", "Pop", "Disco" };

    // Create your view model
    var viewModel = new StoreIndexViewModel
    {
        NumberOfGenres = genres.Count,
        Genres = genres
    };

    ViewBag.Starred = new List<string> { "Rock", "Jazz" };

    return this.View(viewModel);
}
```

NOTE

You could also use the syntax **ViewBag["Starred"]** to access the properties.

2. The star icon **"starred.png"** is included in the **Source\Assets\Images** folder of this lab. In order to add it to the application, drag their content from a **Windows Explorer** window into the **Solution Explorer** in Visual Web Developer Express, as shown below:

Adding star image to the solution

3. Open the view **Store/Index.cshtml** and modify the content. You will read the "starred" property in the **ViewBag** collection, and ask if the current genre name is in the list. In that case you will show a star icon right to the genre link. (C#)

```
@model MvcMusicStore.ViewModels.StoreIndexViewModel

@{
     ViewBag.Title = "Browse Genres";
}

<h2>Browse Genres</h2>

<p>Select from @Model.NumberOfGenres genres</p>

<ul>
     @foreach (string genreName in Model.Genres)
     {
          <li>
                @Html.ActionLink(genreName, "Browse", new { genre = genreName }, null)

                @if (ViewBag.Starred.Contains(genreName))
                {
                     <img src="../../Content/Images/starred.png" alt="Starred element" />
                }
          </li>
     }
</ul>
<br />
<h5><img src="../../Content/Images/starred.png" alt="Starred element" />Starred genres 20% Off!</h5>
```

Task 11 - Running the Application

In this task, you will test that the starred genres display a star icon.

1. Press **F5** to run the Application.
2. The project starts in the **Home** page. Change the URL to **/Store** to verify that each featured genre has the respecting label:

Browsing Genres with starred elements

Exercise 7: A lap around ASP.NET MVC 4 new template

In this exercise, you will explore the enhancements in the ASP.NET MVC 4 project templates, taking a look at the most relevant features of the new template.

Task 1: Exploring the ASP.NET MVC 4 Internet Application Template

1. If not already open, start **VS Express for Web**

2. Select the **File | New | Project** menu command. In the **New Project** dialog, select the **Visual C#|Web** template on the left pane tree, and choose the **ASP.NET MVC 4 Web Application**. **Name** the project *MusicStore* and update the **solution name** to *Begin*, then select a location (or leave the default) and click **OK**.

Creating a new ASP.NET MVC 4 Project

3. In the **New ASP.NET MVC 4 Project** dialog, select the **Internet Application** project template and click **OK**. Notice you can select either Razor or ASPX as the view engine.

Creating a new ASP.NET MVC 4 Internet Application

> **NOTE**
>
> Razor syntax has been introduced in ASP.NET MVC 3. Its goal is to minimize the number of characters and keystrokes required in a file, enabling a fast and fluid coding workflow. Razor leverages existing C#/VB (or other) language skills and delivers a template markup syntax that enables an awesome HTML construction workflow.

4. Press **F5** to run the solution and see the renewed template. You can check out the following features:

   a. **Modern-style templates**

      The templates have been renewed, providing more modern-looking styles.

ASP.NET MVC 4 restyled templates

b. **Adaptive Rendering**

Check out resizing the browser window and notice how the page layout dynamically adapts to the new window size. These templates use the adaptive rendering technique to render properly in both desktop and mobile platforms without any customization.

ASP.NET MVC 4 project template in different browser sizes

5. Close the browser to stop the debugger and return to Visual Studio.

6. Now you are able to explore the solution and check out some of the new features introduced by ASP.NET MVC 4 in the project template.

The ASP.NET MVC 4 Internet Application Project Template

a. **HTML5 markup**

Browse template views to find out the new theme markup, for example open **About.cshtml** view within **Home** folder.

```
    <p>
        Use this area to provide additional information.
    </p>
</article>

<aside>
    <h3>Aside Title</h3>
    <p>
        Use this area to provide additional information.
    </p>
    <ul>
        <li>@Html.ActionLink("Home", "Index", "Home")</li>
        <li>@Html.ActionLink("About", "About", "Home")</li>
        <li>@Html.ActionLink("Contact", "Contact", "Home")</li>
    </ul>
</aside>
```

New template, using Razor and HTML5 markup

b. **JavaScript libraries included**

a. **jQuery**: jQuery simplifies HTML document traversing, event handling, animating, and Ajax interactions.

b. **jQuery UI**: This library provides abstractions for low-level interaction and animation,

advanced effects and themeable widgets, built on top of the jQuery JavaScript Library.

> **NOTE**
>
> You can learn about jQuery and jQuery UI in http://docs.jquery.com/.

c. **KnockoutJS**: The ASP.NET MVC 4 default template now includes **KnockoutJS**, a JavaScript MVVM framework that lets you create rich and highly responsive web applications using JavaScript and HTML. Like in ASP.NET MVC 3, jQuery and jQuery UI libraries are also included in ASP.NET MVC 4.

> **NOTE**
>
> You can get more information about KnockOutJS library in this link: http://learn.knockoutjs.com/.

d. **Modernizr**: This library runs automatically, making your site compatible with older browsers when using HTML5 and CSS3 technologies.

> **NOTE**
>
> You can get more information about Modernizr library in this link: http://www.modernizr.com/.

c. **SimpleMembership included in the solution**

SimpleMembership has been designed as a replacement for the previous ASP.NET Role and Membership provider system. It has many new features that make it easier for the developer to secure web pages in a more flexible way.

The Internet template already has set up a few things to integrate SimpleMembership, for example, the AccountController is prepared to use OAuthWebSecurity (for OAuth account registration, login, management, etc.) and Web Security.

SimpleMembership Included in the solution

> **NOTE**
> Find more information about OAuthWebSecurity in MSDN.

> **NOTE**
> Additionally, you can deploy this application to Windows Azure Web Sites following Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy.

Summary

By completing this Hands-On Lab you have learned the fundamentals of ASP.NET MVC:

- The core elements of an MVC application and how they interact
- How to create an ASP.NET MVC Application
- How to add and configure Controllers to handle parameters passed through the URL and querystring
- How to add a layout master page to setup a template for common HTML content, a StyleSheet to enhance the look and feel and a View template to display HTML content
- How to use the ViewModel pattern for passing properties to the View template to display dynamic information
- How to use parameters passed to Controllers in the View template
- How to add links to pages inside the ASP.NET MVC application
- How to add and use dynamic properties in a View
- The enhancements in the ASP.NET MVC 4 project templates

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy

This appendix will show you how to create a new web site from the Windows Azure Management Portal and publish the application you obtained by following the lab, taking advantage of the Web Deploy publishing feature provided by Windows Azure.

Task 1 - Creating a New Web Site from the Windows Azure Portal

1. Go to the Windows Azure Management Portal and sign in using the Microsoft credentials associated with your subscription.

> **NOTE**
> With Windows Azure you can host 10 ASP.NET Web Sites for free and then scale as your traffic grows. You can sign up here.

Log on to Windows Azure Management Portal

2. Click **New** on the command bar.

Creating a new Web Site

3. Click **Compute | Web Site**. Then select **Quick Create** option. Provide an available URL for the new web site and click **Create Web Site**.

> **NOTE**
>
> A Windows Azure Web Site is the host for a web application running in the cloud that you can control and manage. The Quick Create option allows you to deploy a completed web application to the Windows Azure Web Site from outside the portal. It does not include steps for setting up a database.

Creating a new Web Site using Quick Create

4. Wait until the new **Web Site** is created.

5. Once the Web Site is created click the link under the **URL** column. Check that the new Web Site is working.

Browsing to the new web site

Web site running

6. Go back to the portal and click the name of the web site under the **Name** column to display the management pages.

Opening the Web Site management pages

7. In the **Dashboard** page, under the **quick glance** section, click the **Download publish profile** link.

> **NOTE**
>
> The *publish profile* contains all of the information required to publish a web application to a Windows Azure website for each enabled publication method. The publish profile contains the URLs, user credentials and database strings required to connect to and authenticate against each of the endpoints for which a publication method is enabled. **Microsoft WebMatrix 2**, **Microsoft Visual Studio Express for Web** and **Microsoft Visual Studio 2012** support reading publish profiles to automate configuration of these programs for publishing web applications to Windows Azure websites.

Downloading the Web Site publish profile

8. Download the publish profile file to a known location. Further in this exercise you will see how to use this file to publish a web application to a Windows Azure Web Sites from Visual Studio.

Saving the publish profile file

Task 2 - Configuring the Database Server

If your application makes use of SQL Server databases you will need to create a SQL Database server. If you want to deploy a simple application that does not use SQL Server you might skip this task.

1. You will need a SQL Database server for storing the application database. You can view the SQL Database servers from your subscription in the Windows Azure Management portal at **Sql Databases | Servers | Server's Dashboard**. If you do not have a server created, you can create one using the **Add** button on the command bar. Take note of the **server name and URL, administrator login name and password**, as you will use them in the next tasks. Do not create the database yet, as it will be created in a later stage.

SQL Database Server Dashboard

2. In the next task you will test the database connection from Visual Studio, for that reason you need to include your local IP address in the server's list of **Allowed IP Addresses**. To do that, click **Configure**, select the IP address from **Current Client IP Address** and paste it on the **Start IP Address** and **End IP Address** text boxes and click the ✔ button.

Adding Client IP Address

3. Once the **Client IP Address** is added to the allowed IP addresses list, click on **Save** to confirm the changes.

Confirm Changes

Task 3 - Publishing an ASP.NET MVC 4 Application using Web Deploy

1. Go back to the ASP.NET MVC 4 solution. In the **Solution Explorer**, right-click the web site project and select **Publish**.

Publishing the web site

2. Import the publish profile you saved in the first task.

Importing publish profile

3. Click **Validate Connection**. Once Validation is complete click **Next**.

> **NOTE**
>
> Validation is complete once you see a green checkmark appear next to the Validate Connection button.

Validating connection

4. In the **Settings** page, under the **Databases** section, click the button next to your database connection's textbox (i.e. **DefaultConnection**).

Web deploy configuration

5. Configure the database connection as follows:

   - In the **Server name** type your SQL Database server URL using the *tcp:* prefix.
   - In **User name** type your server administrator login name.
   - In **Password** type your server administrator login password.
   - Type a new database name, for example: *MVC4SampleDB*.

Configuring destination connection string

6. Then click **OK**. When prompted to create the database click **Yes**.

Creating the database

7. The connection string you will use to connect to SQL Database in Windows Azure is shown within Default Connection textbox. Then click **Next**.

Connection string pointing to SQL Database

8. In the **Preview** page, click **Publish**.

Publishing the web application

9. Once the publishing process finishes, your default browser will open the published web site.

Application published to Windows Azure

Appendix C: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Models and Data Access

2/20/2020 • 27 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

This Hands-on Lab assumes you have basic knowledge of **ASP.NET MVC**. If you have not used **ASP.NET MVC** before, we recommend you to go over **ASP.NET MVC 4 Fundamentals** Hands-on Lab.

This lab walks you through the enhancements and new features previously described by applying minor changes to a sample Web application provided in the Source folder.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Models and Data Access.

In **ASP.NET MVC Fundamentals** Hands-on Lab, you have been passing hard-coded data from the Controllers to the View templates. But, in order to build a real Web application, you might want to use a real database.

This Hands-on Lab will show you how to use a database engine in order to store and retrieve the data needed for the Music Store application. To accomplish that, you will start with an existing database and create the Entity Data Model from it. Throughout this lab, you will meet the **Database First** approach as well as the **Code First** approach.

However, you can also use the **Model First** approach, create the same model using the tools, and then generate the database from it.

Database First vs. Model First

After generating the Model, you will make the proper adjustments in the StoreController to provide the Store Views with the data taken from the database, instead of using hard-coded data. You will not need to make any change to the View templates because the StoreController will be returning the same ViewModels to the View templates, although this time the data will come from the database.

The Code First Approach

The Code First approach allows us to define the model from the code without generating classes that are generally coupled with the framework.

In code first, model objects are defined with POCOs, "Plain Old CLR Objects". POCOs are simple plain classes that have no inheritance and do not implement interfaces. We can automatically generate the database from them, or we can use an existing database and generate the class mapping from the code.

The benefits of using this approach is that the Model remains independent from the persistence framework (in this case, Entity Framework), as the POCOs classes are not coupled with the mapping framework.

> **NOTE**
> This Lab is based on ASP.NET MVC 4 and a version of the Music Store sample application customized and minimized to fit only the features shown in this Hands-On Lab.
>
> If you wish to explore the whole **Music Store** tutorial application you can find it in MVC-Music-Store.

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix A for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run **.\Source\Setup\CodeSnippets.vsi** file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix C: Using Code Snippets".

Exercises

This Hands-on Lab is comprised by the following exercises:

1. Exercise 1: Adding a Database
2. Exercise 2: Creating a Database using Code First
3. Exercise 3: Querying the Database with Parameters

> **NOTE**
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **35 minutes**.

Exercise 1: Adding a Database

In this exercise, you will learn how to add a database with the tables of the MusicStore application to the solution in order to consume its data. Once the database is generated with the model, and added to the solution, you will modify the StoreController class to provide the View template with the data taken from the database, instead of using hard-coded values.

Task 1 - Adding a Database

In this task, you will add an already created database with the main tables of the MusicStore application to the solution.

1. Open the **Begin** solution located at **Source/Ex1-AddingADatabaseDBFirst/Begin/** folder.
    a. You will need to download some missing NuGet packages before continue. To do this, click the

Project menu and select **Manage NuGet Packages**.

b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Add **MvcMusicStore** database file. In this Hands-on Lab, you will use an already created database called **MvcMusicStore.mdf**. To do that, right-click **App_Data** folder, point to **Add** and then click **Existing Item**. Browse to **\Source\Assets** and select the **MvcMusicStore.mdf** file.

Adding an Existing Item

MvcMusicStore.mdf database file

The database has been added to the project. Even when the database is located inside the solution, you can query and update it as it was hosted in a different database server.

MvcMusicStore database in Solution Explorer

3. Verify the connection to the database. To do this, double-click **MvcMusicStore.mdf** to establish a connection.

Connecting to MvcMusicStore.mdf

Task 2 - Creating a Data Model

In this task, you will create a data model to interact with the database added in the previous task.

1. Create a data model that will represent the database. To do this, in Solution Explorer right-click the **Models** folder, point to **Add** and then click **New Item**. In the **Add New Item** dialog, select the **Data** template and then the **ADO.NET Entity Data Model** item. Change the data model name to **StoreDB.edmx** and click **Add**.

Adding the StoreDB ADO.NET Entity Data Model

2. The **Entity Data Model Wizard** will appear. This wizard will guide you through the creation of the model layer. Since the model should be created based on the existing database recently added, select **Generate from database** and click **Next**.

Choosing the model content

3. Since you are generating a model from a database, you will need to specify the connection to use. Click **New Connection**.

4. Select **Microsoft SQL Server Database File** and click **Continue**.

Choose data source dialog

5. Click **Browse** and select the database **MvcMusicStore.mdf** you located in the **App_Data** folder and click **OK**.

Connection properties

6. The generated class should have the same name as the entity connection string, so change its name to **MusicStoreEntities** and click **Next**.

Choosing the data connection

7. Choose the database objects to use. As the Entity Model will use just the database's tables, select the **Tables** option, and make sure that the **Include foreign key columns in the model** and **Pluralize or singularize generated object names** options are also selected. Change the Model Namespace to **MvcMusicStore.Model** and click **Finish**.

Choosing the database objects

> **NOTE**
>
> If a Security Warning dialog is shown, click **OK** to run the template and generate the classes for the model entities.

8. An entity diagram for the database will appear, while a separate class that maps each table to the database will be created. For example, the **Albums** table will be represented by an **Album** class, where each column in the table will map to a class property. This will allow you to query and work with objects that represent rows in the database.

Entity diagram

> **NOTE**
>
> The T4 templates (.tt) run code to generate the entities classes and will overwrite the existing classes with the same name. In this example, the classes "Album", "Genre" and "Artist" were overwritten with the generated code.

Task 3 - Building the Application

In this task, you will check that, although the model generation have removed the **Album**, **Genre** and **Artist** model classes, the project builds successfully by using the new data model classes.

1. Build the project by selecting the **Build** menu item and then **Build MvcMusicStore**.

Building the project

2. The project builds successfully. Why does it still work? It works because the database tables have fields that include the properties that you were using in the removed classes **Album** and **Genre**.

Builds succeeded

3. While the designer displays the entities in a diagram format, they are really C# classes. Expand the **StoreDB.edmx** node in the Solution Explorer and then **StoreDB.tt**, you will see the new generated entities.

Generated files

Task 4 - Querying the Database

In this task, you will update the StoreController class so that, instead of using hardcoded data, it will query the database to retrieve the information.

1. Open **Controllers\StoreController.cs** and add the following field to the class to hold an instance of the **MusicStoreEntities** class, named **storeDB**:

   (Code Snippet - *Models And Data Access - Ex1 storeDB*)

```
public class StoreController : Controller
{
    private MusicStoreEntities storeDB = new MusicStoreEntities();
```

2. The **MusicStoreEntities** class exposes a collection property for each table in the database. Update **Browse** action method to retrieve a Genre with all of the **Albums**.

   (Code Snippet - *Models And Data Access - Ex1 Store Browse*)

```
public ActionResult Browse(string genre)
{
    // Retrieve Genre and its Associated Albums from database
    var genreModel = new Genre
    {
        Name = genre,
        Albums = this.storeDB.Albums.ToList()
    };

    return this.View(genreModel);
}
```

> **NOTE**
>
> You are using a capability of .NET called **LINQ** (language-integrated query) to write strongly-typed query expressions against these collections - which will execute code against the database and return objects that you can program against.
>
> For more information about LINQ, please visit the msdn site.

3. Update **Index** action method to retrieve all the genres.

   (Code Snippet - *Models And Data Access - Ex1 Store Index*)

```
public ActionResult Index()
{
    var genres = this.storeDB.Genres;

    return this.View(genres);
}
```

4. Update **Index** action method to retrieve all the genres and transform the collection to a list.

   (Code Snippet - *Models And Data Access - Ex1 Store GenreMenu*)

```
// GET: /Store/GenreMenu
[ChildActionOnly]
public ActionResult GenreMenu()
{
    var genres = this.storeDB.Genres.Take(9).ToList();

    return this.PartialView(genres);
}
```

Task 5 - Running the Application

In this task, you will check that the Store Index page will now display the Genres stored in the database instead of the hardcoded ones. There is no need to change the View template because the **StoreController** is returning the same entities as before, although this time the data will come from the database.

1. Rebuild the solution and press **F5** to run the Application.

2. The project starts in the Home page. Verify that the menu of **Genres** is no longer a hardcoded list, and the data is directly retrieved from the database.

Browsing Genres from the database

3. Now browse to any genre and verify the albums are populated from database.

Browsing Albums from the database

Exercise 2: Creating a Database Using Code First

In this exercise, you will learn how to use the Code First approach to create a database with the tables of the MusicStore application, and how to access its data.

Once the model is generated, you will modify the StoreController to provide the View template with the data taken from the database, instead of using hardcoded values.

> **NOTE**
> If you have completed Exercise 1 and have already worked with the Database First approach, you will now learn how to get the same results with a different process. The tasks that are in common with Exercise 1 have been marked to make your reading easier. If you have not completed Exercise 1 but would like to learn the Code First approach, you can start from this exercise and get a full coverage of the topic.

Task 1 - Populating Sample Data

In this task, you will populate the database with sample data when it is initially created using Code-First.

1. Open the **Begin** solution located at **Source/Ex2-CreatingADatabaseCodeFirst/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Add the **SampleData.cs** file to the **Models** folder. To do that, right-click **Models** folder, point to **Add** and then click **Existing Item**. Browse to **\Source\Assets** and select the **SampleData.cs** file.

Sample data populate code

3. Open the **Global.asax.cs** file and add the following *using* statements.

   (Code Snippet - *Models And Data Access - Ex2 Global Asax Usings*)

```
using MvcMusicStore.Models;
using System.Data.Entity;
```

4. In the **Application_Start()** method add the following line to set the database initializer.

   (Code Snippet - *Models And Data Access - Ex2 Global Asax SetInitializer*)

```
protected void Application_Start()
{
    AreaRegistration.RegisterAllAreas();

    WebApiConfig.Register(GlobalConfiguration.Configuration);
    FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
    RouteConfig.RegisterRoutes(RouteTable.Routes);
    BundleConfig.RegisterBundles(BundleTable.Bundles);

    Database.SetInitializer(new SampleData());
}
```

Task 2 - Configuring the connection to the Database

Now that you have already added a database to our project, you will write in the **Web.config** file the connection string.

1. Add a connection string at **Web.config**. To do that, open **Web.config** at project root and replace the connection string named DefaultConnection with this line in the **<connectionStrings>** section:

Web.config file location

```
<configuration>
...
  <connectionStrings>
    <add name="MusicStoreEntities" connectionString="data source=(LocalDb)\v11.0;initial
catalog=MvcMusicStore;Integrated Security=SSPI;AttachDBFilename=|DataDirectory|\MvcMusicStore.mdf"
providerName="System.Data.SqlClient" />
  </connectionStrings>
...
```

Task 3 - Working with the Model

Now that you have already configured the connection to the database, you will link the model with the database tables. In this task, you will create a class that will be linked to the database with Code First. Remember that there is an existent POCO model class that should be modified.

> **NOTE**
>
> If you completed Exercise 1, you will note that this step was performed by a wizard. By doing Code First, you will manually create classes that will be linked to data entities.

1. Open the POCO model class **Genre** from **Models** project folder and include an ID. Use an int property with the name **GenreId**.

   (Code Snippet - *Models And Data Access - Ex2 Code First Genre*)

```
namespace MvcMusicStore.Models
{
    using System.Collections.Generic;

    public class Genre
    {
      public int GenreId { get; set; }

      public string Name { get; set; }

      public string Description { get; set; }

      public List<Album> Albums { get; set; }
    }
}
```

   > **NOTE**
   >
   > To work with Code First conventions, the class Genre must have a primary key property that will be automatically detected.
   >
   > You can read more about Code First Conventions in this msdn article.

2. Now, open the POCO model class **Album** from **Models** project folder and include the foreign keys, create properties with the names **GenreId** and **ArtistId**. This class already have the **GenreId** for the primary key.

   (Code Snippet - *Models And Data Access - Ex2 Code First Album*)

```
namespace MvcMusicStore.Models
{
    public class Album
    {
        public int AlbumId { get; set; }

        public int GenreId { get; set; }

        public int ArtistId { get; set; }

        public string Title { get; set; }

        public decimal Price { get; set; }

        public string AlbumArtUrl { get; set; }

        public virtual Genre Genre { get; set; }

        public virtual Artist Artist { get; set; }
    }
}
```

3. Open the POCO model class **Artist** and include the **ArtistId** property.

   (Code Snippet - *Models And Data Access - Ex2 Code First Artist*)

```
namespace MvcMusicStore.Models
{
    public class Artist
    {
        public int ArtistId { get; set; }

        public string Name { get; set; }
    }
}
```

4. Right-click the **Models** project folder and select **Add | Class**. Name the file **MusicStoreEntities.cs**. Then, click **Add**.

Adding a new item

Adding a class

5. Open the class you have just created, **MusicStoreEntities.cs**, and include the namespaces **System.Data.Entity** and **System.Data.Entity.Infrastructure**.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Data.Entity;
using System.Data.Entity.Infrastructure;
...
```

6. Replace the class declaration to extend the **DbContext** class: declare a public **DBSet** and override **OnModelCreating** method. After this step you will get a domain class that will link your model with the Entity Framework. In order to do that, replace the class code with the following:

   (Code Snippet - *Models And Data Access - Ex2 Code First MusicStoreEntities*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Data.Entity;
using System.Data.Entity.Infrastructure;

namespace MvcMusicStore.Models
{
    public class MusicStoreEntities : DbContext
    {
        public DbSet<Genre> Genres { get; set; }

        public DbSet<Album> Albums { get; set; }

        public DbSet<Artist> Artists { get; set; }

        protected override void OnModelCreating(DbModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Genre>().ToTable("Genres");
            modelBuilder.Entity<Album>().ToTable("Albums");
            modelBuilder.Entity<Artist>().ToTable("Artists");

            base.OnModelCreating(modelBuilder);
        }
    }
}
```

NOTE

With Entity Framework **DbContext** and **DBSet** you will be able to query the POCO class Genre. By extending **OnModelCreating** method, you are specifying in the **code** how Genre will be mapped to a database table. You can find more information about DBContext and DBSet in this msdn article: link

Task 4 - Querying the Database

In this task, you will update the StoreController class so that, instead of using hardcoded data, it will retrieve it from the database.

NOTE

This task is in common with Exercise 1.

If you completed Exercise 1 you will note these steps are the same in both approaches (Database first or Code first). They are different in how the data is linked with the model, but the access to data entities is yet transparent from the controller.

1. Open **Controllers\StoreController.cs** and add the following field to the class to hold an instance of the **MusicStoreEntities** class, named **storeDB**:

   (Code Snippet - *Models And Data Access - Ex1 storeDB*)

```
public class StoreController : Controller
{
    private MusicStoreEntities storeDB = new MusicStoreEntities();
    ...
}
```

2. The **MusicStoreEntities** class exposes a collection property for each table in the database. Update **Browse** action method to retrieve a Genre with all of the **Albums**.

(Code Snippet - *Models And Data Access - Ex2 Store Browse*)

```
public ActionResult Browse(string genre)
{
     // Retrieve Genre and its Associated Albums from database
     var genreModel = new Genre
    {
        Name = genre,
        Albums = this.storeDB.Albums.ToList()
    };

     return this.View(genreModel);
}
```

> **NOTE**
>
> You are using a capability of .NET called **LINQ** (language-integrated query) to write strongly-typed query expressions against these collections - which will execute code against the database and return objects that you can program against.
>
> For more information about LINQ, please visit the msdn site.

3. Update **Index** action method to retrieve all the genres.

   (Code Snippet - *Models And Data Access - Ex2 Store Index*)

```
public ActionResult Index()
{
    var genres = this.storeDB.Genres;

    return this.View(genres);
}
```

4. Update **Index** action method to retrieve all the genres and transform the collection to a list.

   (Code Snippet - *Models And Data Access - Ex2 Store GenreMenu*)

```
// GET: /Store/GenreMenu
[ChildActionOnly]
public ActionResult GenreMenu()
{
    var genres = this.storeDB.Genres.Take(9).ToList();

    return this.PartialView(genres);
}
```

Task 5 - Running the Application

In this task, you will check that the Store Index page will now display the Genres stored in the database instead of the hardcoded ones. There is no need to change the View template because the **StoreController** is returning the same **StoreIndexViewModel** as before, but this time the data will come from the database.

1. Rebuild the solution and press **F5** to run the Application.

2. The project starts in the Home page. Verify that the menu of **Genres** is no longer a hardcoded list, and the data is directly retrieved from the database.

Browsing Genres from the database

3. Now browse to any genre and verify the albums are populated from database.

Browsing Albums from the database

Exercise 3: Querying the Database with Parameters

In this exercise, you will learn how to query the database using parameters, and how to use Query Result Shaping, a feature that reduces the number database accesses retrieving data in a more efficient way.

> **NOTE**
>
> For further information on Query Result Shaping, visit the following msdn article.

Task 1 - Modifying StoreController to Retrieve Albums from Database

In this task, you will change the `StoreController` class to access the database to retrieve albums from a specific genre.

1. Open the **Begin** solution located at the **Source\Ex3-QueryingTheDatabaseWithParametersCodeFirst\Begin** folder if you want to use Code-First approach or **Source\Ex3-QueryingTheDatabaseWithParametersDBFirst\Begin** folder if you want to use Database-First approach. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open the **StoreController** class to change the **Browse** action method. To do this, in the **Solution Explorer**, expand the **Controllers** folder and double-click **StoreController.cs**.

3. Change the **Browse** action method to retrieve albums for a specific genre. To do this, replace the following code:

   (Code Snippet - *Models And Data Access - Ex3 StoreController BrowseMethod*)

```
public ActionResult Browse(string genre)
{
    // Retrieve Genre and its Associated Albums from database
    var genreModel = this.storeDB.Genres.Include("Albums")
        .Single(g => g.Name == genre);

    return this.View(genreModel);
}
```

> **NOTE**
> To populate a collection of the entity, you need to use the **Include** method to specify you want to retrieve the albums too. You can use the **.Single()** extension in LINQ because in this case only one genre is expected for an album. The **Single()** method takes a Lambda expression as a parameter, which in this case specifies a single Genre object such that its name matches the value defined.
>
> You will take advantage of a feature that allows you to indicate other related entities you want loaded as well when the Genre object is retrieved. This feature is called **Query Result Shaping**, and enables you to reduce the number of times needed to access the database to retrieve information. In this scenario, you will want to pre-fetch the Albums for the Genre you retrieve.
>
> The query includes **Genres.Include("Albums")** to indicate that you want related albums as well. This will result in a more efficient application, since it will retrieve both Genre and Album data in a single database request.

Task 2 - Running the Application

In this task, you will run the application and retrieve albums of a specific genre from the database.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/Store/Browse?genre=Pop** to verify that the results are being retrieved from the database.

Browsing /Store/Browse?genre=Pop

Task 3 - Accessing Albums by Id

In this task, you will repeat the previous procedure to get albums by their Id.

1. Close the browser if needed, to return to Visual Studio. Open the **StoreController** class to change the **Details** action method. To do this, in the **Solution Explorer**, expand the **Controllers** folder and double-click **StoreController.cs**.

2. Change the **Details** action method to retrieve albums details based on their **Id**. To do this, replace the following code:

   (Code Snippet - *Models And Data Access - Ex3 StoreController DetailsMethod*)

```
// GET: /Store/
public ActionResult Details(int id)
{
    var album = this.storeDB.Albums.Find(id);

    if (album == null)
    {
        return this.HttpNotFound();
    }

    return this.View(album);
}
```

Task 4 - Running the Application

In this task, you will run the Application in a web browser and obtain album details by their Id.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/Store/Details/51** or browse the genres and select an album to verify that the results are being retrieved from the database.

Browsing /Store/Details/51

> **NOTE**
>
> Additionally, you can deploy this application to Windows Azure Web Sites following Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy.

Summary

By completing this Hands-on Lab you have learned the fundamentals of ASP.NET MVC Models and Data Access, using the **Database First** approach as well as the **Code First** Approach:

- How to add a database to the solution in order to consume its data
- How to update Controllers to provide View templates with the data taken from the database instead of hard-coded one
- How to query the database using parameters
- How to use the Query Result Shaping, a feature that reduces the number of database accesses, retrieving data in a more efficient way
- How to use both Database First and Code First approaches in Microsoft Entity Framework to link the database with the model

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy

This appendix will show you how to create a new web site from the Windows Azure Management Portal and publish the application you obtained by following the lab, taking advantage of the Web Deploy publishing feature provided by Windows Azure.

Task 1 - Creating a New Web Site from the Windows Azure Portal

1. Go to the Windows Azure Management Portal and sign in using the Microsoft credentials associated with your subscription.

> **NOTE**
> With Windows Azure you can host 10 ASP.NET Web Sites for free and then scale as your traffic grows. You can sign up here.

Log on to Windows Azure Management Portal

2. Click **New** on the command bar.

Creating a new Web Site

3. Click **Compute | Web Site**. Then select **Quick Create** option. Provide an available URL for the new web site and click **Create Web Site**.

> **NOTE**
>
> A Windows Azure Web Site is the host for a web application running in the cloud that you can control and manage. The Quick Create option allows you to deploy a completed web application to the Windows Azure Web Site from outside the portal. It does not include steps for setting up a database.

Creating a new Web Site using Quick Create

4. Wait until the new **Web Site** is created.

5. Once the Web Site is created click the link under the **URL** column. Check that the new Web Site is working.

Browsing to the new web site

Web site running

6. Go back to the portal and click the name of the web site under the **Name** column to display the management pages.

Opening the Web Site management pages

7. In the **Dashboard** page, under the **quick glance** section, click the **Download publish profile** link.

> **NOTE**
>
> The *publish profile* contains all of the information required to publish a web application to a Windows Azure website for each enabled publication method. The publish profile contains the URLs, user credentials and database strings required to connect to and authenticate against each of the endpoints for which a publication method is enabled. **Microsoft WebMatrix 2**, **Microsoft Visual Studio Express for Web** and **Microsoft Visual Studio 2012** support reading publish profiles to automate configuration of these programs for publishing web applications to Windows Azure websites.

Downloading the Web Site publish profile

8. Download the publish profile file to a known location. Further in this exercise you will see how to use this file to publish a web application to a Windows Azure Web Sites from Visual Studio.

Saving the publish profile file

Task 2 - Configuring the Database Server

If your application makes use of SQL Server databases you will need to create a SQL Database server. If you want to deploy a simple application that does not use SQL Server you might skip this task.

1. You will need a SQL Database server for storing the application database. You can view the SQL Database servers from your subscription in the Windows Azure Management portal at **Sql Databases | Servers | Server's Dashboard**. If you do not have a server created, you can create one using the **Add** button on the command bar. Take note of the **server name and URL, administrator login name and password**, as you will use them in the next tasks. Do not create the database yet, as it will be created in a later stage.

SQL Database Server Dashboard

2. In the next task you will test the database connection from Visual Studio, for that reason you need to include your local IP address in the server's list of **Allowed IP Addresses**. To do that, click **Configure**, select the IP address from **Current Client IP Address** and paste it on the **Start IP Address** and **End IP Address** text boxes and click the ✔ button.

Adding Client IP Address

3. Once the **Client IP Address** is added to the allowed IP addresses list, click on **Save** to confirm the changes.

Confirm Changes

Task 3 - Publishing an ASP.NET MVC 4 Application using Web Deploy

1. Go back to the ASP.NET MVC 4 solution. In the **Solution Explorer**, right-click the web site project and select **Publish**.

Publishing the web site

2. Import the publish profile you saved in the first task.

Importing publish profile

3. Click **Validate Connection**. Once Validation is complete click **Next**.

> **NOTE**
>
> Validation is complete once you see a green checkmark appear next to the Validate Connection button.

Validating connection

4. In the **Settings** page, under the **Databases** section, click the button next to your database connection's textbox (i.e. **DefaultConnection**).

Web deploy configuration

5. Configure the database connection as follows:

   - In the **Server name** type your SQL Database server URL using the *tcp:* prefix.
   - In **User name** type your server administrator login name.
   - In **Password** type your server administrator login password.
   - Type a new database name.

Configuring destination connection string

6. Then click **OK**. When prompted to create the database click **Yes**.

Creating the database

7. The connection string you will use to connect to SQL Database in Windows Azure is shown within Default Connection textbox. Then click **Next**.

Connection string pointing to SQL Database

8. In the **Preview** page, click **Publish**.

Publishing the web application

9. Once the publishing process finishes, your default browser will open the published web site.

Appendix C: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

```
namespace PhotoGallery.Controllers
{
    public class PhotoController : Controller
    {
        mvc
    }
}
```

IMvcFilter
MVC4LabEx02HomeControllerUsings
MVC4LabEx02IndexAction
MVC4LabEx02PhotoController
MVC4LabEx02Photomodel
MVC4LabEx03iPhoneDisplayMode
MVC4LabEx04Attributes
MVC4LabEx04GetAsync
MVC4LabEx04SendAsyncwithCancellationTok

MVC4 Lab - Ex02 - PhotoController

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Custom Action Filters

2/20/2020 • 20 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

ASP.NET MVC provides Action Filters for executing filtering logic either before or after an action method is called. Action Filters are custom attributes that provide declarative means to add pre-action and post-action behavior to the controller's action methods.

In this Hands-on Lab you will create a custom action filter attribute into MvcMusicStore solution to catch controller's requests and log the activity of a site into a database table. You will be able to add your logging filter by injection to any controller or action. Finally, you will see the log view that shows the list of visitors.

This Hands-on Lab assumes you have basic knowledge of **ASP.NET MVC**. If you have not used **ASP.NET MVC** before, we recommend you to go over **ASP.NET MVC 4 Fundamentals** Hands-on Lab.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available from at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Custom Action Filters.

Objectives

In this Hands-On Lab, you will learn how to:

- Create a custom action filter attribute to extend filtering capabilities
- Apply a custom filter attribute by injection to a specific level
- Register a custom action filters globally

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix A for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run **.\Source\Setup\CodeSnippets.vsi** file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix C: Using Code Snippets".

Exercises

This Hands-On Lab is comprised by the following exercises:

1. Exercise 1: Logging actions
2. Exercise 2: Managing Multiple Action Filters

Estimated time to complete this lab: **30 minutes**.

> **NOTE**
>
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Exercise 1: Logging Actions

In this exercise, you will learn how to create a custom action log filter by using ASP.NET MVC 4 Filter Providers. For that purpose you will apply a logging filter to the MusicStore site that will record all the activities in the selected controllers.

The filter will extend **ActionFilterAttributeClass** and override **OnActionExecuting** method to catch each request and then perform the logging actions. The context information about HTTP requests, executing methods, results and parameters will be provided by ASP.NET MVC **ActionExecutingContext** class .

> **NOTE**
>
> ASP.NET MVC 4 also has default filters providers you can use without creating a custom filter. ASP.NET MVC 4 provides the following types of filters:
>
> - **Authorization** filter, which makes security decisions about whether to execute an action method, such as performing authentication or validating properties of the request.
> - **Action** filter, which wraps the action method execution. This filter can perform additional processing, such as providing extra data to the action method, inspecting the return value, or canceling execution of the action method
> - **Result** filter, which wraps execution of the ActionResult object. This filter can perform additional processing of the result, such as modifying the HTTP response.
> - **Exception** filter, which executes if there is an unhandled exception thrown somewhere in action method, starting with the authorization filters and ending with the execution of the result. Exception filters can be used for tasks such as logging or displaying an error page.
>
> For more information about Filters Providers please visit this MSDN link: (https://msdn.microsoft.com/library/dd410209.aspx) .

About MVC Music Store Application logging feature

This Music Store solution has a new data model table for site logging, **ActionLog**, with the following fields: Name of the controller that received a request, Called action, Client IP and Time stamp.

Data model - ActionLog table

The solution provides an ASP.NET MVC View for the Action log that can be found at **MvcMusicStores/Views/ActionLog**:

Action Log view

With this given structure, all the work will be focused on interrupting controller's request and performing the logging by using custom filtering.

Task 1 - Creating a Custom Filter to Catch a Controller's Request

In this task you will create a custom filter attribute class that will contain the logging logic. For that purpose you will extend ASP.NET MVC **ActionFilterAttribute** Class and implement the interface **IActionFilter**.

> **NOTE**
>
> The **ActionFilterAttribute** is the base class for all the attribute filters. It provides the following methods to execute a specific logic after and before controller action's execution:
>
> - **OnActionExecuting**(ActionExecutingContext filterContext): Just before the action method is called.
> - **OnActionExecuted**(ActionExecutedContext filterContext): After the action method is called and before the result is executed (before view render).
> - **OnResultExecuting**(ResultExecutingContext filterContext): Just before the result is executed (before view render).
> - **OnResultExecuted**(ResultExecutedContext filterContext): After the result is executed (after the view is rendered).
>
> By overriding any of these methods into a derived class, you can execute your own filtering code.

1. Open the **Begin** solution located at **\Source\Ex01-LoggingActions\Begin** folder.

   a. You will need to download some missing NuGet packages before you continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.
>
> For more information, see this article: http://docs.nuget.org/docs/workflows/using-nuget-without-committing-packages.

2. Add a new C# class into the **Filters** folder and name it *CustomActionFilter.cs*. This folder will store all the custom filters.

3. Open **CustomActionFilter.cs** and add a reference to **System.Web.Mvc** and **MvcMusicStore.Models** namespaces:

   (Code Snippet - *ASP.NET MVC 4 Custom Action Filters - Ex1-CustomActionFilterNamespaces*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.Models;
```

4. Inherit the **CustomActionFilter** class from **ActionFilterAttribute** and then make **CustomActionFilter** class implement **IActionFilter** interface.

```
//...
namespace MvcMusicStore.Filters
{
    public class CustomActionFilter : ActionFilterAttribute, IActionFilter
    {
        //...
    }
}
```

5. Make **CustomActionFilter** class override the method **OnActionExecuting** and add the necessary logic to log the filter's execution. To do this, add the following highlighted code within **CustomActionFilter** class.

   (Code Snippet - *ASP.NET MVC 4 Custom Action Filters - Ex1-LoggingActions*)

```
public class CustomActionFilter : ActionFilterAttribute, IActionFilter
{
    void IActionFilter.OnActionExecuting(ActionExecutingContext filterContext)
    {
        // TODO: Add your action filter's tasks here

        // Log Action Filter call
        using (MusicStoreEntities storeDb = new MusicStoreEntities())
        {
            ActionLog log = new ActionLog()
            {
                Controller = filterContext.ActionDescriptor.ControllerDescriptor.ControllerName,
                Action = string.Concat(filterContext.ActionDescriptor.ActionName, " (Logged By: Custom
Action Filter)"),
                IP = filterContext.HttpContext.Request.UserHostAddress,
                DateTime = filterContext.HttpContext.Timestamp
            };
            storeDb.ActionLogs.Add(log);
            storeDb.SaveChanges();
            OnActionExecuting(filterContext);
        }
    }
}
```

NOTE

OnActionExecuting method is using **Entity Framework** to add a new ActionLog register. It creates and fills a new entity instance with the context information from **filterContext**.

You can read more about **ControllerContext** class at msdn.

Task 2 - Injecting a Code Interceptor into the Store Controller Class

In this task you will add the custom filter by injecting it to all controller classes and controller actions that will be logged. For the purpose of this exercise, the Store Controller class will have a log.

The method **OnActionExecuting** from **ActionLogFilterAttribute** custom filter runs when an injected element is called.

It is also possible to intercept a specific controller method.

1. Open the **StoreController** at **MvcMusicStore\Controllers** and add a reference to the **Filters** namespace:

```
using System.Linq;
using System.Web.Mvc;
using MvcMusicStore.Models;
using MvcMusicStore.Filters;
```

2. Inject the custom filter **CustomActionFilter** into **StoreController** class by adding **[CustomActionFilter]** attribute before the class declaration.

```
...
[CustomActionFilter]
public class StoreController : Controller
{
    ...
}
```

NOTE

When a filter is injected into a controller class, all its actions are also injected. If you would like to apply the filter only for a set of actions, you would have to inject **[CustomActionFilter]** to each one of them:

```
[CustomActionFilter]
public ActionResult Index()
{
  ...
}

[CustomActionFilter]
public ActionResult Browse(string genre)
{
  ...
}
```

Task 3 - Running the Application

In this task, you will test that the logging filter is working. You will start the application and visit the store, and then you will check logged activities.

1. Press **F5** to run the application.
2. Browse to **/ActionLog** to see log view initial state:

Log tracker status before page activity

NOTE

By default, it will always show one item that is generated when retrieving the existing genres for the menu.

For simplicity purposes we're cleaning up the **ActionLog** table each time the application runs so it will only show the logs of each particular task's verification.

You might need to remove the following code from the **Session_Start** method (in the **Global.asax** class), in order to save an historical log for all the actions executed within the Store Controller.

```
// Clean up Logs Table
MusicStoreEntities storeDB = new MusicStoreEntities();
foreach (var log in

storeDB.ActionLogs.ToList())
{
   storeDB.ActionLogs.Remove(log);
}

storeDB.SaveChanges();
```

3. Click one of the **Genres** from the menu and perform some actions there, like browsing an available album.
4. Browse to **/ActionLog** and if the log is empty press **F5** to refresh the page. Check that your visits were tracked:

Action log with activity logged

Exercise 2: Managing Multiple Action Filters

In this exercise you will add a second Custom Action Filter to the StoreController class and define the specific order in which both filters will be executed. Then you will update the code to register the filter Globally.

There are different options to take into account when defining the Filters' execution order. For example, the Order

property and the Filters' scope:

You can define a **Scope** for each of the Filters, for example, you could scope all the Action Filters to run within the **Controller Scope**, and all Authorization Filters to run in **Global scope**. The scopes have a defined execution order.

Additionally, each action filter has an Order property which is used to determine the execution order in the scope of the filter.

For more information about Custom Action Filters execution order, please visit this MSDN article: (https://msdn.microsoft.com/library/dd381609(v=vs.98).aspx).

Task 1: Creating a new Custom Action Filter

In this task, you will create a new Custom Action Filter to inject into the StoreController class, learning how to manage the execution order of the filters.

1. Open the **Begin** solution located at **\Source\Ex02-ManagingMultipleActionFilters\Begin** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   >
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.
   >
   > For more information, see this article: http://docs.nuget.org/docs/workflows/using-nuget-without-committing-packages.

2. Add a new C# class into the **Filters** folder and name it *MyNewCustomActionFilter.cs*

3. Open **MyNewCustomActionFilter.cs** and add a reference to **System.Web.Mvc** and the **MvcMusicStore.Models** namespace:

   (Code Snippet - *ASP.NET MVC 4 Custom Action Filters - Ex2-MyNewCustomActionFilterNamespaces*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.Models;
```

4. Replace the default class declaration with the following code.

   (Code Snippet - *ASP.NET MVC 4 Custom Action Filters - Ex2-MyNewCustomActionFilterClass*)

```
public class MyNewCustomActionFilter : ActionFilterAttribute, IActionFilter
{
  void IActionFilter.OnActionExecuting(ActionExecutingContext filterContext)

  {
        // TODO: Add your acction filter's tasks here

        // Log Action Filter Call
        MusicStoreEntities storeDB = new MusicStoreEntities();

        ActionLog log = new ActionLog()
        {
             Controller = filterContext.ActionDescriptor.ControllerDescriptor.ControllerName,
             Action = filterContext.ActionDescriptor.ActionName + " (Logged By:

MyNewCustomActionFilter)",
             IP = filterContext.HttpContext.Request.UserHostAddress,
             DateTime = filterContext.HttpContext.Timestamp
        };

        storeDB.ActionLogs.Add(log);
        storeDB.SaveChanges();

        this.OnActionExecuting(filterContext);
  }
}
```

NOTE

This Custom Action Filter is almost the same than the one you created in the previous exercise. The main difference is that it has the *"Logged By"* attribute updated with this new class' name to identify which filter registered the log.

Task 2: Injecting a new Code Interceptor into the StoreController Class

In this task, you will add a new custom filter into the StoreController Class and run the solution to verify how both filters work together.

1. Open the **StoreController** class located at **MvcMusicStore\Controllers** and inject the new custom filter **MyNewCustomActionFilter** into **StoreController** class like is shown in the following code.

```
[MyNewCustomActionFilter]
[CustomActionFilter]
public class StoreController : Controller
{
...
}
```

2. Now, run the application in order to see how these two Custom Action Filters work. To do this, press **F5** and wait until the application starts.

3. Browse to **/ActionLog** to see log view initial state.

Log tracker status before page activity

4. Click one of the **Genres** from the menu and perform some actions there, like browsing an available album.
5. Check that this time; your visits were tracked twice: once for each of the Custom Action Filters you added in the **StorageController** class.

Action log with activity logged

6. Close the browser.

Task 3: Managing Filter Ordering

In this task, you will learn how to manage the filters' execution order by using the Order property.

1. Open the **StoreController** class located at **MvcMusicStore\Controllers** and specify the **Order** property in both filters like shown below.

```
[MyNewCustomActionFilter(Order = 2)]
[CustomActionFilter(Order = 1)]
public class StoreController : Controller
{
...
}
```

2. Now, verify how the filters are executed depending on its Order property's value. You will find that the filter with the smallest Order value (**CustomActionFilter**) is the first one that is executed. Press **F5** and wait until the application starts.

3. Browse to **/ActionLog** to see log view initial state.

Log tracker status before page activity

4. Click one of the **Genres** from the menu and perform some actions there, like browsing an available album.
5. Check that this time, your visits were tracked ordered by the filters' Order value: **CustomActionFilter** logs' first.

Action log with activity logged

6. Now, you will update the Filters' order value and verify how the logging order changes. In the **StoreController** class, update the Filters' Order value like shown below.

```
[MyNewCustomActionFilter(Order = 1)]
[CustomActionFilter(Order = 2)]
public class StoreController : Controller
{
...
}
```

7. Run the application again by pressing **F5**.

8. Click one of the **Genres** from the menu and perform some actions there, like browsing an available album.

9. Check that this time, the logs created by **MyNewCustomActionFilter** filter appears first.

Action log with activity logged

Task 4: Registering Filters Globally

In this task, you will update the solution to register the new filter (**MyNewCustomActionFilter**) as a global filter. By doing this, it will be triggered by all the actions performed in the application and not only in the StoreController ones as in the previous task.

1. In **StoreController** class, remove **[MyNewCustomActionFilter]** attribute and the order property from **[CustomActionFilter]**. It should look like the following:

```
[CustomActionFilter]
public class StoreController : Controller
{
...
}
```

2. Open **Global.asax** file and locate the **Application_Start** method. Notice that each time the application starts it is registering the global filters by calling **RegisterGlobalFilters** method within **FilterConfig** class.

```
protected void Application_Start()
{
    AreaRegistration.RegisterAllAreas();

    WebApiConfig.Register(GlobalConfiguration.Configuration);
    FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
    RouteConfig.RegisterRoutes(RouteTable.Routes);
    BundleConfig.RegisterBundles(BundleTable.Bundles);

    AppConfig.Configure();
}
```

Registering Global Filters in Global.asax

3. Open **FilterConfig.cs** file within **App_Start** folder.

4. Add a reference to using System.Web.Mvc; using MvcMusicStore.Filters; namespace.

```
using System.Web.Mvc;
using MvcMusicStore.Filters;
```

5. Update **RegisterGlobalFilters** method adding your custom filter. To do this, add the highlighted code:

```
public static void RegisterGlobalFilters(GlobalFilterCollection filters)
{
    filters.Add(new HandleErrorAttribute());
    filters.Add(new MyNewCustomActionFilter());
}
```

6. Run the application by pressing **F5**.

7. Click one of the **Genres** from the menu and perform some actions there, like browsing an available album.

8. Check that now **[MyNewCustomActionFilter]** is being injected in HomeController and ActionLogController too.

Action log with global activity logged

> **NOTE**
>
> Additionally, you can deploy this application to Windows Azure Web Sites following Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy.

Summary

By completing this Hands-On Lab you have learned how to extend an action filter to execute custom actions. You have also learned how to inject any filter to your page controllers. The following concepts were used:

- How to create Custom Action filters with the ASP.NET MVC ActionFilterAttribute class
- How to inject filters into ASP.NET MVC controllers
- How to manage filter ordering using the Order property
- How to register filters globally

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Publishing an ASP.NET MVC 4 Application using Web Deploy

This appendix will show you how to create a new web site from the Windows Azure Management Portal and publish the application you obtained by following the lab, taking advantage of the Web Deploy publishing feature provided by Windows Azure.

Task 1 - Creating a New Web Site from the Windows Azure Portal

1. Go to the Windows Azure Management Portal and sign in using the Microsoft credentials associated with your subscription.

> **NOTE**
>
> With Windows Azure you can host 10 ASP.NET Web Sites for free and then scale as your traffic grows. You can sign up here.

Log on to Windows Azure Management Portal

2. Click **New** on the command bar.

Creating a new Web Site

3. Click **Compute | Web Site**. Then select **Quick Create** option. Provide an available URL for the new web site and click **Create Web Site**.

> **NOTE**
>
> A Windows Azure Web Site is the host for a web application running in the cloud that you can control and manage. The Quick Create option allows you to deploy a completed web application to the Windows Azure Web Site from outside the portal. It does not include steps for setting up a database.

Creating a new Web Site using Quick Create

4. Wait until the new **Web Site** is created.

5. Once the Web Site is created click the link under the **URL** column. Check that the new Web Site is working.

Browsing to the new web site

Web site running

6. Go back to the portal and click the name of the web site under the **Name** column to display the management pages.

Opening the Web Site management pages

7. In the **Dashboard** page, under the **quick glance** section, click the **Download publish profile** link.

> **NOTE**
>
> The *publish profile* contains all of the information required to publish a web application to a Windows Azure website for each enabled publication method. The publish profile contains the URLs, user credentials and database strings required to connect to and authenticate against each of the endpoints for which a publication method is enabled. **Microsoft WebMatrix 2**, **Microsoft Visual Studio Express for Web** and **Microsoft Visual Studio 2012** support reading publish profiles to automate configuration of these programs for publishing web applications to Windows Azure websites.

Downloading the Web Site publish profile

8. Download the publish profile file to a known location. Further in this exercise you will see how to use this file to publish a web application to a Windows Azure Web Sites from Visual Studio.

Saving the publish profile file

Task 2 - Configuring the Database Server

If your application makes use of SQL Server databases you will need to create a SQL Database server. If you want to deploy a simple application that does not use SQL Server you might skip this task.

1. You will need a SQL Database server for storing the application database. You can view the SQL Database servers from your subscription in the Windows Azure Management portal at **Sql Databases | Servers | Server's Dashboard**. If you do not have a server created, you can create one using the **Add** button on the command bar. Take note of the **server name and URL, administrator login name and password**, as you will use them in the next tasks. Do not create the database yet, as it will be created in a later stage.

SQL Database Server Dashboard

2. In the next task you will test the database connection from Visual Studio, for that reason you need to include your local IP address in the server's list of **Allowed IP Addresses**. To do that, click **Configure**, select the IP address from **Current Client IP Address** and paste it on the **Start IP Address** and **End IP Address** text

boxes and click the ✔ button.

Adding Client IP Address

3. Once the **Client IP Address** is added to the allowed IP addresses list, click on **Save** to confirm the changes.

Confirm Changes

Task 3 - Publishing an ASP.NET MVC 4 Application using Web Deploy

1. Go back to the ASP.NET MVC 4 solution. In the **Solution Explorer**, right-click the web site project and select **Publish**.

Publishing the web site

2. Import the publish profile you saved in the first task.

Importing publish profile

3. Click **Validate Connection**. Once Validation is complete click **Next**.

> **NOTE**
>
> Validation is complete once you see a green checkmark appear next to the Validate Connection button.

Validating connection

4. In the **Settings** page, under the **Databases** section, click the button next to your database connection's textbox (i.e. **DefaultConnection**).

Web deploy configuration

5. Configure the database connection as follows:

   - In the **Server name** type your SQL Database server URL using the *tcp:* prefix.
   - In **User name** type your server administrator login name.
   - In **Password** type your server administrator login password.
   - Type a new database name.

Configuring destination connection string

6. Then click **OK**. When prompted to create the database click **Yes**.

Creating the database

7. The connection string you will use to connect to SQL Database in Windows Azure is shown within Default Connection textbox. Then click **Next**.

Connection string pointing to SQL Database

8. In the **Preview** page, click **Publish**.

Publishing the web application

9. Once the publishing process finishes, your default browser will open the published web site.

Appendix C: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Entity Framework Scaffolding and Migrations

2/20/2020 • 9 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

If you are familiar with ASP.NET MVC 4 controller methods, or have completed the "Helpers, Forms and Validation" Hands-On lab, you should be aware that many of the logic to create, update, list and remove any data entity it is repeated among the application. Not to mention that, if your model has several classes to manipulate, you will be likely to spend a considerable time writing the POST and GET action methods for each entity operation, as well as each of the views.

In this lab you will learn how to use the ASP.NET MVC 4 scaffolding to automatically generate the baseline of your application's CRUD (Create, Read, Update and Delete). Starting from a simple model class, and, without writing a single line of code, you will create a controller that will contain all the CRUD operations, as well as the all the necessary views. After building and running the simple solution, you will have the application database generated, together with the MVC logic and views for data manipulation.

In addition, you will learn how easy it is to use Entity Framework Migrations to perform model updates throughout your entire application. Entity Framework Migrations will let you modify your database after the model has changed with simple steps. With all these in mind, you will be able to build and maintain web applications more efficiently, taking advantage of the latest features of ASP.NET MVC 4.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available from at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Entity Framework Scaffolding and Migrations.

Objectives

In this Hands-On Lab, you will learn how to:

- Use ASP.NET scaffolding for CRUD operations in controllers.
- Change the database model using Entity Framework Migrations.

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix A for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run `.\Source\Setup\CodeSnippets.vsi` file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix B: Using Code Snippets".

Exercises

The following exercise make up this Hands-On Lab:

1. Using ASP.NET MVC 4 Scaffolding with Entity Framework Migrations

> **NOTE**
>
> This exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercise. You can use this solution as a guide if you need additional help working through the exercise.

Estimated time to complete this lab: **30 minutes**

Exercise 1: Using ASP.NET MVC 4 Scaffolding with Entity Framework Migrations

ASP.NET MVC scaffolding provides a quick way to generate the CRUD operations in a standardized way, creating the necessary logic that lets your application interact with the database layer.

In this exercise, you will learn how to use ASP.NET MVC 4 scaffolding with code first to create the CRUD methods. Then, you will learn how to update your model applying the changes in the database by using Entity Framework Migrations.

Task 1- Creating a new ASP.NET MVC 4 project using Scaffolding

1. If not already open, start **Visual Studio 2012**.

2. Select **File | New Project**. In the New Project dialog, under the **Visual C# | Web** section, select **ASP.NET MVC 4 Web Application**. Name the project to **MVC4andEFMigrations** and set the location to **Source\Ex1-UsingMVC4ScaffoldingEFMigrations** folder of this lab. Set the **Solution name** to **Begin** and ensure **Create directory for solution** is checked. Click **OK**.

New ASP.NET MVC 4 Project Dialog Box

3. In the **New ASP.NET MVC 4 Project** dialog box select the **Internet Application** template, and make sure that **Razor** is the selected **View engine**. Click **OK** to create the project.

New ASP.NET MVC 4 Internet Application

4. In the Solution Explorer, right-click **Models** and select **Add | Class** to create a simple class person (POCO). Name it **Person** and click **OK**.

5. Open the Person class and insert the following properties.

   (Code Snippet - *ASP.NET MVC 4 and Entity Framework Migrations - Ex1 Person Properties*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;

namespace MVC4EF.Models
{
    public class Person
    {
        public int PersonID { get; set; }

        public string FirstName { get; set; }

        public string LastName { get; set; }
    }
}
```

6. Click **Build | Build Solution** to save the changes and build the project.

Building the Application

7. In the Solution Explorer, right-click the controllers folder and select **Add | Controller**.

8. Name the controller *PersonController* and complete the **Scaffolding options** with the following values.

   a. In the **Template** drop-down list, select the **MVC controller with read/write actions and views, using Entity Framework** option.

   b. In the **Model class** drop-down list, select the **Person** class.

   c. In the **Data Context class** list, select **<New data context...>**. Choose any name and click **OK**.

   d. In the **Views** drop-down list, make sure that **Razor** is selected.

Adding the Person controller with scaffolding

9. Click **Add** to create the new controller for Person with scaffolding. You have now generated the controller actions as well as the views.

After creating the Person controller with scaffolding

10. Open **PersonController** class. Notice that the full CRUD action methods have been generated automatically.

```
//
// GET: /Person/Details/5

public ActionResult Details(int id = 0)...

//
// GET: /Person/Create

public ActionResult Create()...

//
// POST: /Person/Create

[HttpPost]
public ActionResult Create(Person person)...

//
// GET: /Person/Edit/5

public ActionResult Edit(int id = 0)...

//
// POST: /Person/Edit/5

[HttpPost]
public ActionResult Edit(Person person)...

//
// GET: /Person/Delete/5

public ActionResult Delete(int id = 0)...
```

Inside the Person controller

Task 2- Running the application

At this point, the database is not yet created. In this task, you will run the application for the first time and test the CRUD operations. The database will be created on the fly with Code First.

1. Press **F5** to run the application.

2. In the browser, add **/Person** to the URL to open the Person page.

Application: first run

3. You will now explore the Person pages and test the CRUD operations.

   a. Click **Create New** to add a new person. Enter a first name and a last name and click **Create**.

Adding a new person

   b. In the person's list, you can delete, edit or add items.

Person list

c. Click **Details** to open the person's details.

Person's details

4. Close the browser and return to Visual Studio. Notice that you have created the whole CRUD for the person entity throughout your application -from the model to the views- without having to write a single line of code!

Task 3- Updating the database using Entity Framework Migrations

In this task you will update the database using Entity Framework Migrations. You will discover how easy it is to change the model and reflect the changes in your databases by using the Entity Framework Migrations feature.

1. Open the Package Manager Console. Select **Tools** > **NuGet Package Manager** > **Package Manager Console**.

2. In the Package Manager Console, enter the following command:

   PMC

```
Enable-Migrations -ContextTypeName [ContextClassName]
```

Enabling migrations

The Enable-Migration command creates the **Migrations** folder, which contains a script to initialize the database.

Migrations folder

3. Open the **Configuration.cs** file in the Migrations folder. Locate the class constructor and change the **AutomaticMigrationsEnabled** value to *true*.

```
public Configuration()
{
    AutomaticMigrationsEnabled = true;
}
```

4. Open the Person class and add an attribute for the person's middle name. With this new attribute, you are changing the model.

```
public class Person
{
    public int PersonID { get; set; }
    public string FirstName { get; set; }
    public string LastName { get; set; }
    public string MiddleName { get; set; }
}
```

5. Select **Build | Build Solution** on the menu to build the application.

Building the application

6. In the Package Manager Console, enter the following command:

   PMC

   ```
   Add-Migration AddMiddleName
   ```

   This command will look for changes in the data objects, and then, it will add the necessary commands to modify the database accordingly.

Adding a middle name

7. (Optional) You can run the following command to generate a SQL script with the differential update. This will let you update the database manually (In this case it's not necessary), or apply the changes in other databases:

   PMC

   ```
   Update-Database -Script -SourceMigration:

   $InitialDatabase
   ```

Generating a SQL script

SQL Script update

8. In the Package Manager Console, enter the following command to update the database:

PMC

```
Update-Database -Verbose
```

Updating the Database

This will add the **MiddleName** column in the **People** table to match the current definition of the **Person** class.

9. Once the database is updated, right-click the Controller folder and select **Add | Controller** to add the Person controller again (Complete with the same values). This will update the existing methods and views adding the new attribute.

Updating the controller

10. Click **Add**. Then, select the values **Overwrite PersonController.cs** and the **Overwrite associated views** and click **OK**.

Updating the controller

Task4- Running the application

1. Press **F5** to run the application.

2. Open **/Person**. Notice that the data was preserved, while the middle name column was added.

Middle Name added

3. If you click **Edit**, you will be able to add a middle name to the current person.

Summary

In this Hands-On lab, you have learned simple steps to create CRUD operations with ASP.NET MVC 4 Scaffolding using any model class. Then, you have learned how to perform an end to end update in your application -from the database to the views- by using Entity Framework Migrations.

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and

install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Dependency Injection

2/20/2020 • 22 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

This Hands-on Lab assumes you have basic knowledge of **ASP.NET MVC** and **ASP.NET MVC 4 filters**. If you have not used **ASP.NET MVC 4 filters** before, we recommend you to go over **ASP.NET MVC Custom Action Filters** Hands-on Lab.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available from at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Dependency Injection.

In **Object Oriented Programming** paradigm, objects work together in a collaboration model where there are contributors and consumers. Naturally, this communication model generates dependencies between objects and components, becoming difficult to manage when complexity increases.

Class dependencies and model complexity

You have probably heard about the **Factory Pattern** and the separation between the interface and the implementation using services, where the client objects are often responsible for service location.

The Dependency Injection pattern is a particular implementation of Inversion of Control. **Inversion of Control (IoC)** means that objects do not create other objects on which they rely to do their work. Instead, they get the objects that they need from an outside source (for example, an xml configuration file).

Dependency Injection (DI) means that this is done without the object intervention, usually by a framework component that passes constructor parameters and set properties.

The Dependency Injection (DI) Design Pattern

At a high level, the goal of Dependency Injection is that a client class (e.g. *the golfer*) needs something that satisfies an interface (e.g. *IClub*). It doesn't care what the concrete type is (e.g. *WoodClub, IronClub, WedgeClub* or *PutterClub*), it wants someone else to handle that (e.g. a good *caddy*). The Dependency Resolver in ASP.NET MVC can allow you to register your dependency logic somewhere else (e.g. a container or a *bag of clubs*).

Dependency Injection - Golf analogy

The advantages of using Dependency Injection pattern and Inversion of Control are the following:

- Reduces class coupling
- Increases code reusing
- Improves code maintainability
- Improves application testing

> **NOTE**
> Dependency Injection is sometimes compared with Abstract Factory Design Pattern, but there is a slight difference between both approaches. DI has a Framework working behind to solve dependencies by calling the factories and the registered services.

Now that you understand the Dependency Injection Pattern, you will learn throughout this lab how to apply it in ASP.NET MVC 4. You will start using Dependency Injection in the **Controllers** to include a database access service. Next, you will apply Dependency Injection to the **Views** to consume a service and show information. Finally, you will extend the DI to ASP.NET MVC 4 Filters, injecting a custom action filter in the solution.

In this Hands-on Lab, you will learn how to:

- Integrate ASP.NET MVC 4 with Unity for Dependency Injection using NuGet Packages
- Use Dependency Injection inside an ASP.NET MVC Controller
- Use Dependency Injection inside an ASP.NET MVC View
- Use Dependency Injection inside an ASP.NET MVC Action Filter

> **NOTE**
> This Lab is using Unity.Mvc3 NuGet Package for dependency resolution, but it is possible to adapt any Dependency Injection Framework to work with ASP.NET MVC 4.

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix A for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run **.\Source\Setup\CodeSnippets.vsi** file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix B: Using Code Snippets".

Exercises

This Hands-On Lab is comprised by the following exercises:

1. Exercise 1: Injecting a Controller
2. Exercise 2: Injecting a View
3. Exercise 3: Injecting Filters

> **NOTE**
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **30 minutes**.

Exercise 1: Injecting a Controller

In this exercise, you will learn how to use Dependency Injection in ASP.NET MVC Controllers by integrating Unity using a NuGet Package. For that reason, you will include services into your MvcMusicStore controllers to separate the logic from the data access. The services will create a new dependency in the controller constructor, which will be resolved using Dependency Injection with the help of **Unity**.

This approach will show you how to generate less coupled applications, which are more flexible and easier to maintain and test. You will also learn how to integrate ASP.NET MVC with Unity.

About StoreManager Service

The MVC Music Store provided in the begin solution now includes a service that manages the Store Controller data named **StoreService**. Below you will find the Store Service implementation. Note that all the methods return Model entities.

```
namespace MvcMusicStore.Controllers
{
    using System.Web.Mvc;
    using MvcMusicStore.Filters;
    using MvcMusicStore.Services;

    [MyNewCustomActionFilter(Order = 1)]
    [CustomActionFilter(Order = 2)]
    public class StoreController : Controller
    {
        private IStoreService service;

        public StoreController(IStoreService service)
        {
            this.service = service;
        }

        // GET: /Store/
        public ActionResult Details(int id)
        {
            var album = this.service.GetAlbum(id);
            if (album == null)
            {
                return this.HttpNotFound();
            }

            return this.View(album);
        }

        public ActionResult Browse(string genre)
        {
            // Retrieve Genre and its Associated Albums from database
            var genreModel = this.service.GetGenreByName(genre);

            return this.View(genreModel);
        }

        public ActionResult Index()
        {
            var genres = this.service.GetGenres();

            return this.View(genres);
        }

        // GET: /Store/GenreMenu
        public ActionResult GenreMenu()
        {
            var genres = this.service.GetGenres();

            return this.PartialView(genres);
        }
    }
}
```

StoreController from the begin solution now consumes **StoreService**. All the data references were removed from **StoreController**, and now possible to modify the current data access provider without changing any method that consumes **StoreService**.

You will find below that the **StoreController** implementation has a dependency with **StoreService** inside the class constructor.

NOTE

The dependency introduced in this exercise is related to **Inversion of Control** (IoC).

The **StoreController** class constructor receives an **IStoreService** type parameter, which is essential to perform service calls from inside the class. However, **StoreController** does not implement the default constructor (with no parameters) that any controller must have to work with ASP.NET MVC.

To resolve the dependency, the controller has to be created by an abstract factory (a class that returns any object of the specified type).

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.ViewModels;
using MvcMusicStore.Models;
using MvcMusicStore.Services;

namespace MvcMusicStore.Controllers
{
    public class StoreController : Controller
    {
        private IStoreService service;

        public StoreController(IStoreService service)
        {
            this.service = service;
        }

        //
        // GET: /Store/
        public ActionResult Index()
        {
            // Create list of genres
            var genres = this.service.GetGenreNames();

            // Create your view model
            var viewModel = new StoreIndexViewModel
            {
                Genres = genres.ToList(),
                NumberOfGenres = genres.Count()
            };

            return View(viewModel);
        }

        //
        // GET: /Store/Browse?genre=Disco
        public ActionResult Browse(string genre)
        {
            var genreModel = this.service.GetGenreByName(genre);

            var viewModel = new StoreBrowseViewModel()
            {
                Genre = genreModel,
                Albums = genreModel.Albums.ToList()
            };

            return View(viewModel);
        }

        //
        // GET: /Store/Details/5
        public ActionResult Details(int id)
        {
            var album = this.service.GetAlbum(id);

            return View(album);
        }
    }
}
```

> **NOTE**
> You will get an error when the class tries to create the StoreController without sending the service object, as there is no parameterless constructor declared.

Task 1 - Running the Application

In this task, you will run the Begin application, which includes the service into the Store Controller that separates the data access from the application logic.

When running the application, you will receive an exception, as the controller service is not passed as a parameter by default:

1. Open the **Begin** solution located in **Source\Ex01-Injecting Controller\Begin**.
   a. You will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.
   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.
   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Press **Ctrl + F5** to run the application without debugging. You will get the error message "**No parameterless constructor defined for this object**":

Error while running ASP.NET MVC Begin Application

3. Close the browser.

In the following steps you will work on the Music Store Solution to inject the dependency this controller needs.

Task 2 - Including Unity into MvcMusicStore Solution

In this task, you will include **Unity.Mvc3** NuGet Package to the solution.

> **NOTE**
>
> Unity.Mvc3 package was designed for ASP.NET MVC 3, but it is fully compatible with ASP.NET MVC 4.
>
> Unity is a lightweight, extensible dependency injection container with optional support for instance and type interception. It is a general-purpose container for use in any type of .NET application. It provides all the common features found in dependency injection mechanisms including: object creation, abstraction of requirements by specifying dependencies at runtime and flexibility, by deferring the component configuration to the container.

1. Install **Unity.Mvc3** NuGet Package in the **MvcMusicStore** project. To do this, open the **Package Manager Console** from **View | Other Windows**.

2. Run the following command.

   PMC

   ```
   Install-Package Unity.Mvc3
   ```

   
   Installing Unity.Mvc3 NuGet Package

3. Once the **Unity.Mvc3** package is installed, explore the files and folders it automatically adds in order to simplify Unity configuration.

Unity.Mvc3 package installed

Task 3 - Registering Unity in Global.asax.cs Application_Start

In this task, you will update the **Application_Start** method located in **Global.asax.cs** to call the Unity Bootstrapper initializer and then, update the Bootstrapper file registering the Service and Controller you will use for Dependency Injection.

1. Now, you will hook up the Bootstrapper which is the file that initializes the Unity container and Dependency Resolver. To do this, open **Global.asax.cs** and add the following highlighted code within the **Application_Start** method.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex01 - Initialize Unity*)

```
protected void Application_Start()
{
    AreaRegistration.RegisterAllAreas();

    WebApiConfig.Register(GlobalConfiguration.Configuration);
    FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
    RouteConfig.RegisterRoutes(RouteTable.Routes);
    BundleConfig.RegisterBundles(BundleTable.Bundles);

    Bootstrapper.Initialise();

    AppConfig.Configure();
}
```

2. Open **Bootstrapper.cs** file.

3. Include the following namespaces: **MvcMusicStore.Services** and **MusicStore.Controllers**.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex01 - Bootstrapper Adding Namespaces*)

```
using System.Web.Mvc;
using Microsoft.Practices.Unity;
using Unity.Mvc3;
using MvcMusicStore.Services;
using MvcMusicStore.Controllers;
```

4. Replace **BuildUnityContainer** method's content with the following code that registers Store Controller and Store Service.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex01 - Register Store Controller and Service*)

```
private static IUnityContainer BuildUnityContainer()
{
    var container = new UnityContainer();

    container.RegisterType<IStoreService, StoreService>();
    container.RegisterType<IController, StoreController>("Store");

    return container;
}
```

Task 4 - Running the Application

In this task, you will run the application to verify that it can now be loaded after including Unity.

1. Press **F5** to run the application, the application should now load without showing any error message.

Running Application with Dependency Injection

2. Browse to **/Store**. This will invoke **StoreController**, which is now created using **Unity**.

MVC Music Store

3. Close the browser.

In the following exercises you will learn how to extend the Dependency Injection scope to use it inside ASP.NET MVC Views and Action Filters.

Exercise 2: Injecting a View

In this exercise, you will learn how to use Dependency Injection in a view with the new features of ASP.NET MVC 4 for Unity integration. In order to do that, you will call a custom service inside the Store Browse View, which will show a message and an image below.

Then, you will integrate the project with Unity and create a custom dependency resolver to inject the dependencies.

Task 1 - Creating a View that Consumes a Service

In this task, you will create a view that performs a service call to generate a new dependency. The service consists in a simple messaging service included in this solution.

1. Open the **Begin** solution located in the **Source\Ex02-Injecting View\Begin** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.
>
> For more information, see this article: http://docs.nuget.org/docs/workflows/using-nuget-without-committing-packages.

2. Include the **MessageService.cs** and the **IMessageService.cs** classes located in the **Source \Assets** folder in **/Services**. To do this, right-click **Services** folder and select **Add Existing Item**. Browse to the files' location and include them.

Adding Message Service and Service Interface

> **NOTE**
>
> The **IMessageService** interface defines two properties implemented by the **MessageService** class. These properties -**Message** and **ImageUrl**- store the message and the URL of the image to be displayed.

3. Create the folder **/Pages** in the project's root folder, and then add the existing class **MyBasePage.cs** from **Source\Assets**. The base page you will inherit from has the following structure.

```
namespace MvcMusicStore.Pages
{
    using System;
    using System.Collections.Generic;
    using System.Linq;
    using System.Web;
    using Microsoft.Practices.Unity;
    using MvcMusicStore.Models;
    using MvcMusicStore.Services;

    public class MyBasePage : System.Web.Mvc.WebViewPage<Genre>
    {
        [Dependency]
        public IMessageService MessageService { get; set; }

        public override void

        Execute()
        {
        }
    }
}
```

4. Open **Browse.cshtml** view from **/Views/Store** folder, and make it inherit from **MyBasePage.cs**.

```
@inherits MvcMusicStore.Pages.MyBasePage
@{
     ViewBag.Title = "Browse Albums";
}
```

5. In the **Browse** view, add a call to **MessageService** to display an image and a message retrieved by the service. (C#)

```
@inherits MvcMusicStore.Pages.MyBasePage
@{
    Viewbag.Title = "Browse Albums";
}
<div>
    @this.MessageService.Message
    <br />
    <img alt="@this.MessageService.Message" src="@this.MessageService.ImageUrl" />
</div>
...
```

Task 2 - Including a Custom Dependency Resolver and a Custom View Page Activator

In the previous task, you injected a new dependency inside a view to perform a service call inside it. Now, you will resolve that dependency by implementing the ASP.NET MVC Dependency Injection interfaces **IViewPageActivator** and **IDependencyResolver**. You will include in the solution an implementation of **IDependencyResolver** that will deal with the service retrieval by using Unity. Then, you will include another custom implementation of **IViewPageActivator** interface that will solve the creation of the views.

NOTE

Since ASP.NET MVC 3, the implementation for Dependency Injection had simplified the interfaces to register services. **IDependencyResolver** and **IViewPageActivator** are part of ASP.NET MVC 3 features for Dependency Injection.

- **IDependencyResolver** interface replaces the previous IMvcServiceLocator. Implementers of IDependencyResolver must return an instance of the service or a service collection.

```
public interface IDependencyResolver {
    object GetService(Type serviceType);
    IEnumerable<object> GetServices(Type serviceType);
}
```

- **IViewPageActivator** interface provides more fine-grained control over how view pages are instantiated via dependency injection. The classes that implement **IViewPageActivator** interface can create view instances using context information.

```
public interface IViewPageActivator {
    object Create(ControllerContext controllerContext, Type type);
}
```

1. Create the **/Factories** folder in the project's root folder.

2. Include **CustomViewPageActivator.cs** to your solution from **/Sources/Assets/** to **Factories** folder. To do that, right-click the **/Factories** folder, select **Add | Existing Item** and then select **CustomViewPageActivator.cs**. This class implements the **IViewPageActivator** interface to hold the Unity Container.

```
namespace MvcMusicStore.Factories
{
    using System;
    using System.Collections.Generic;
    using System.Linq;
    using System.Web;
    using System.Web.Mvc;
    using Microsoft.Practices.Unity;

    public class CustomViewPageActivator : IViewPageActivator
    {
        private IUnityContainer container;

        public CustomViewPageActivator(IUnityContainer container)
        {
            this.container = container;
        }

        public object Create(ControllerContext controllerContext, Type type)
        {
            return this.container.Resolve(type);
        }
    }
}
```

NOTE

CustomViewPageActivator is responsible for managing the creation of a view by using a Unity container.

3. Include **UnityDependencyResolver.cs** file from **/Sources/Assets** to **/Factories** folder. To do that, right-click the **/Factories** folder, select **Add | Existing Item** and then select **UnityDependencyResolver.cs** file.

```
namespace MvcMusicStore.Factories
{
     using System;
     using System.Collections.Generic;
     using System.Linq;
     using System.Web;
     using System.Web.Mvc;
     using Microsoft.Practices.Unity;

     public class UnityDependencyResolver : IDependencyResolver
     {
          private IUnityContainer container;

          private IDependencyResolver resolver;

          public UnityDependencyResolver(IUnityContainer container, IDependencyResolver resolver)
          {
                this.container = container;
                this.resolver = resolver;
          }

          public object GetService(Type serviceType)
          {
                try
                {
                     return this.container.Resolve(serviceType);
                }
                catch
                {
                     return this.resolver.GetService(serviceType);
                }
          }

          public IEnumerable<object> GetServices(Type serviceType)
          {
                try
                {
                     return this.container.ResolveAll(serviceType);
                }
                catch
                {
                     return this.resolver.GetServices(serviceType);
                }
          }
     }
}
```

NOTE

UnityDependencyResolver class is a custom DependencyResolver for Unity. When a service cannot be found inside the Unity container, the base resolver is invocated.

In the following task both implementations will be registered to let the model know the location of the services and the views.

Task 3 - Registering for Dependency Injection within Unity container

In this task, you will put all the previous things together to make Dependency Injection work.

Up to now your solution has the following elements:

- A **Browse** View that inherits from **MyBaseClass** and consumes **MessageService**.
- An intermediate class -**MyBaseClass**- that has dependency injection declared for the service interface.
- A service - **MessageService** - and its interface **IMessageService**.

- A custom dependency resolver for Unity - **UnityDependencyResolver** - that deals with service retrieval.
- A View Page activator - **CustomViewPageActivator** - that creates the page.

To inject **Browse** View, you will now register the custom dependency resolver in the Unity container.

1. Open **Bootstrapper.cs** file.

2. Register an instance of **MessageService** into the Unity container to initialize the service:

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex02 - Register Message Service*)

```
private static IUnityContainer BuildUnityContainer()
{
    var container = new UnityContainer();

    container.RegisterType<IStoreService, StoreService>();
    container.RegisterType<IController, StoreController>("Store");

    container.RegisterInstance<IMessageService>(new MessageService
    {
        Message = "You are welcome to our Web Camps Training Kit!",
        ImageUrl = "/Content/Images/webcamps.png"
    });
    //...
}
```

3. Add a reference to **MvcMusicStore.Factories** namespace.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex02 - Factories Namespace*)

```
using System.Web.Mvc;
using Microsoft.Practices.Unity;
using Unity.Mvc3;
using MvcMusicStore.Services;
using MvcMusicStore.Controllers;
using MvcMusicStore.Factories;
```

4. Register **CustomViewPageActivator** as a View Page activator into the Unity container:

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex02 - Register CustomViewPageActivator*)

```
private static IUnityContainer BuildUnityContainer()
{
    var container = new UnityContainer();

    container.RegisterType<IStoreService, StoreService>();
    container.RegisterType<IController, StoreController>("Store");

    container.RegisterInstance<IMessageService>(new MessageService
    {
        Message = "You are welcome to our Web Camps Training Kit!",
        ImageUrl = "/Content/Images/webcamps.png"
    });

    container.RegisterType<IViewPageActivator, CustomViewPageActivator>(new
InjectionConstructor(container));

    return container;
}
```

5. Replace ASP.NET MVC 4 default dependency resolver with an instance of **UnityDependencyResolver**. To

do this, replace **Initialize** method content with the following code:

(Code Snippet - *ASP.NET Dependency Injection Lab - Ex02 - Update Dependency Resolver*)

```
public static void Initialise()
{
    var container = BuildUnityContainer();

    DependencyResolver.SetResolver(new Unity.Mvc3.UnityDependencyResolver(container));

    IDependencyResolver resolver = DependencyResolver.Current;

    IDependencyResolver newResolver = new Factories.UnityDependencyResolver(container, resolver);

    DependencyResolver.SetResolver(newResolver);
}
```

> **NOTE**
>
> ASP.NET MVC provides a default dependency resolver class. To work with custom dependency resolvers as the one we have created for unity, this resolver has to be replaced.

Task 4 - Running the Application

In this task, you will run the application to verify that the Store Browser consumes the service and shows the image and the message retrieved:

1. Press **F5** to run the application.
2. Click **Rock** within the Genres Menu and see how the **MessageService** was injected to the view and loaded the welcome message and the image. In this example, we are entering to "**Rock**":

MVC Music Store - View Injection

3. Close the browser.

Exercise 3: Injecting Action Filters

In the previous Hands-On lab **Custom Action Filters** you have worked with filters customization and injection. In this exercise, you will learn how to inject filters with Dependency Injection by using the Unity container. To do that, you will add to the Music Store solution a custom action filter that will trace the activity of the site.

Task 1 - Including the Tracking Filter in the Solution

In this task, you will include in the Music Store a custom action filter to trace events. As custom action filter concepts are already treated in the previous Lab "Custom Action Filters", you will just include the filter class from the Assets folder of this lab, and then create a Filter Provider for Unity:

1. Open the **Begin** solution located in the **Source\Ex03 - Injecting Action Filter\Begin** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   >
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.
   >
   > For more information, see this article: http://docs.nuget.org/docs/workflows/using-nuget-without-committing-packages.

2. Include **TraceActionFilter.cs** file from **/Sources/Assets** to **/Filters** folder.

```
namespace MvcMusicStore.Filters
{
    using System;
    using System.Collections.Generic;
    using System.Linq;
    using System.Web;
    using System.Web.Mvc;

    public class TraceActionFilter : IActionFilter
    {
        public void OnActionExecuted(ActionExecutedContext filterContext)
        {
            filterContext.HttpContext.Trace.Write("OnActionExecuted");
            filterContext.HttpContext.Trace.Write("Action " +
filterContext.ActionDescriptor.ActionName);
            filterContext.HttpContext.Trace.Write("Controller " +
filterContext.ActionDescriptor.ControllerDescriptor.ControllerName);
        }

        public void OnActionExecuting(ActionExecutingContext filterContext)
        {
            filterContext.HttpContext.Trace.Write("OnActionExecuting");
            filterContext.HttpContext.Trace.Write("Action " +
filterContext.ActionDescriptor.ActionName);
            filterContext.HttpContext.Trace.Write("Controller " +
filterContext.ActionDescriptor.ControllerDescriptor.ControllerName);
        }
    }
}
```

> **NOTE**
> This custom action filter performs ASP.NET tracing. You can check "ASP.NET MVC 4 local and Dynamic Action Filters" Lab for more reference.

3. Add the empty class **FilterProvider.cs** to the project in the folder **/Filters.**

4. Add the **System.Web.Mvc** and **Microsoft.Practices.Unity** namespaces in **FilterProvider.cs**.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex03 - Filter Provider Adding Namespaces*)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using Microsoft.Practices.Unity;

namespace MvcMusicStore.Filters
{
     public class FilterProvider
     {
     }
}
```

5. Make the class inherit from **IFilterProvider** Interface.

```
namespace MvcMusicStore.Filters
{
    public class FilterProvider : IFilterProvider
    {
    }
}
```

6. Add a **IUnityContainer** property in the **FilterProvider** class, and then create a class constructor to assign the container.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex03 - Filter Provider Constructor*)

```
public class FilterProvider : IFilterProvider
{
    private IUnityContainer container;

    public FilterProvider(IUnityContainer container)
    {
        this.container = container;
    }
}
```

> **NOTE**
> The filter provider class constructor is not creating a **new** object inside. The container is passed as a parameter, and the dependency is solved by Unity.

7. In the **FilterProvider** class, implement the method **GetFilters** from **IFilterProvider** interface.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex03 - Filter Provider GetFilters*)

```
public class FilterProvider : IFilterProvider
{
    private IUnityContainer container;

    public FilterProvider(IUnityContainer container)
    {
        this.container = container;
    }

    public IEnumerable<Filter> GetFilters(ControllerContext controllerContext, ActionDescriptor
actionDescriptor)
    {
        foreach (IActionFilter actionFilter in this.container.ResolveAll<IActionFilter>())
        {
            yield return new Filter(actionFilter, FilterScope.First, null);
        }
    }
}
```

Task 2 - Registering and Enabling the Filter

In this task, you will enable site tracking. To do that, you will register the filter in **Bootstrapper.cs** **BuildUnityContainer** method to start tracing:

1. Open **Web.config** located in the project root and enable trace tracking at System.Web group.

```
<system.web>
    <trace enabled="true"/>
    <compilation debug="true" targetFramework="4.5">
```

2. Open **Bootstrapper.cs** at project root.

3. Add a reference to the **MvcMusicStore.Filters** namespace.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex03 - Bootstrapper Adding Namespaces*)

```
using System.Web.Mvc;
using Microsoft.Practices.Unity;
using Unity.Mvc3;
using MvcMusicStore.Services;
using MvcMusicStore.Controllers;
using MvcMusicStore.Factories;
using MvcMusicStore.Filters;
```

4. Select the **BuildUnityContainer** method and register the filter in the Unity Container. You will have to register the filter provider as well as the action filter.

   (Code Snippet - *ASP.NET Dependency Injection Lab - Ex03 - Register FilterProvider and ActionFilter*)

```
private static IUnityContainer BuildUnityContainer()
{
    var container = new UnityContainer();

    //...

    container.RegisterInstance<IFilterProvider>("FilterProvider", new FilterProvider(container));
    container.RegisterInstance<IActionFilter>("LogActionFilter", new TraceActionFilter());

    return container;
}
```

Task 3 - Running the Application

In this task, you will run the application and test that the custom action filter is tracing the activity:

1. Press **F5** to run the application.

2. Click **Rock** within the Genres Menu. You can browse to more genres if you want to.

Music Store

3. Browse to **/Trace.axd** to see the Application Trace page, and then click **View Details**.

Application Trace Log

Application Trace - Request Details

4. Close the browser.

Summary

By completing this Hands-On Lab you have learned how to use Dependency Injection in ASP.NET MVC 4 by integrating Unity using a NuGet Package. To achieve that, you have used Dependency Injection inside controllers, views and action filters.

The following concepts were covered:

- ASP.NET MVC 4 Dependency Injection features
- Unity integration using Unity.Mvc3 NuGet Package
- Dependency Injection in Controllers
- Dependency Injection in Views
- Dependency injection of Action Filters

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Helpers, Forms and Validation

2/20/2020 • 35 minutes to read • Edit Online

By Web Camps Team

Download Web Camps Training Kit

In **ASP.NET MVC 4 Models and Data Access** Hands-on Lab, you have been loading and displaying data from the database. In this Hands-on Lab, you will add to the **Music Store** application the ability to edit that data.

With that goal in mind, you will first create the controller that will support the Create, Read, Update and Delete (CRUD) actions of albums. You will generate an Index View template taking advantage of ASP.NET MVC's scaffolding feature to display the albums' properties in an HTML table. To enhance that view, you will add a custom HTML helper that will truncate long descriptions.

Afterwards, you will add the Edit and Create Views that will let you alter the albums in the database, with the help of form elements like dropdowns.

Lastly, you will let users delete an album and also you will prevent them from entering wrong data by validating their input.

This Hands-on Lab assumes you have basic knowledge of **ASP.NET MVC**. If you have not used **ASP.NET MVC** before, we recommend you to go over **ASP.NET MVC Fundamentals** Hands-on Lab.

This lab walks you through the enhancements and new features previously described by applying minor changes to a sample Web application provided in the Source folder.

> **NOTE**
>
> All sample code and snippets are included in the Web Camps Training Kit, available at Microsoft-Web/WebCampTrainingKit Releases. The project specific to this lab is available at ASP.NET MVC 4 Helpers, Forms and Validation.

Objectives

In this Hands-On Lab, you will learn how to:

- Create a controller to support CRUD operations
- Generate an Index View to display entity properties in an HTML table
- Add a custom HTML helper
- Create and customize an Edit View
- Differentiate between action methods that react to either HTTP-GET or HTTP-POST calls
- Add and customize a Create View
- Handle the deletion of an entity
- Validate user input

Prerequisites

You must have the following items to complete this lab:

- Microsoft Visual Studio Express 2012 for Web or superior (read Appendix A for instructions on how to install it).

Setup

Installing Code Snippets

For convenience, much of the code you will be managing along this lab is available as Visual Studio code snippets. To install the code snippets run **.\Source\Setup\CodeSnippets.vsi** file.

If you are not familiar with the Visual Studio Code Snippets, and want to learn how to use them, you can refer to the appendix from this document "Appendix B: Using Code Snippets".

Exercises

The following exercises make up this Hands-On Lab:

1. Creating the Store Manager controller and its Index view
2. Adding an HTML Helper
3. Creating the Edit View
4. Adding a Create View
5. Handling Deletion
6. Adding Validation
7. Using Unobtrusive jQuery at Client Side

> **NOTE**
> Each exercise is accompanied by an **End** folder containing the resulting solution you should obtain after completing the exercises. You can use this solution as a guide if you need additional help working through the exercises.

Estimated time to complete this lab: **60 minutes**

Exercise 1: Creating the Store Manager controller and its Index view

In this exercise, you will learn how to create a new controller to support CRUD operations, customize its Index action method to return a list of albums from the database and finally generating an Index View template taking advantage of ASP.NET MVC's scaffolding feature to display the albums' properties in an HTML table.

Task 1 - Creating the StoreManagerController

In this task, you will create a new controller called **StoreManagerController** to support CRUD operations.

1. Open the **Begin** solution located at **Source/Ex1-CreatingTheStoreManagerController/Begin/** folder.
   a. You will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.
   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.
   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Add a new controller. To do this, right-click the **Controllers** folder within the Solution Explorer, select **Add** and then the **Controller** command. Change the **Controller Name** to **StoreManagerController** and make sure the option **MVC controller with empty read/write actions** is selected. Click **Add**.

Add Controller Dialog

A new Controller class is generated. Since you indicated to add actions for read/write, stub methods for those, common CRUD actions are created with TODO comments filled in, prompting to include the application specific logic.

Task 2 - Customizing the StoreManager Index

In this task, you will customize the StoreManager Index action method to return a View with the list of albums from the database.

1. In the StoreManagerController class, add the following *using* directives.

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex1 using MvcMusicStore*)

```
using System.Data;
using System.Data.Entity;
using MvcMusicStore.Models;
```

2. Add a field to the **StoreManagerController** to hold an instance of **MusicStoreEntities.**

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex1 MusicStoreEntities*)

```
public class StoreManagerController : Controller
{
    private MusicStoreEntities db = new MusicStoreEntities();
```

3. Implement the StoreManagerController Index action to return a View with the list of albums.

   The Controller action logic will be very similar to the StoreController's Index action written earlier. Use LINQ to retrieve all albums, including Genre and Artist information for display.

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex1 StoreManagerController Index*)

```
//
// GET: /StoreManager/

public ActionResult Index()
{
    var albums = this.db.Albums.Include(a => a.Genre).Include(a => a.Artist)
         .OrderBy(a => a.Price);

    return this.View(albums.ToList());
}
```

Task 3 - Creating the Index View

In this task, you will create the Index View template to display the list of albums returned by the **StoreManager** Controller.

1. Before creating the new View template, you should build the project so that the **Add View Dialog** knows about the **Album** class to use. Select **Build | Build MvcMusicStore** to build the project.

2. Right-click inside the **Index** action method and select **Add View**. This will bring up the **Add View** dialog.

Adding a View from within the Index method

3. In the Add View dialog, verify that the View Name is **Index**. Select the **Create a strongly-typed view** option, and select **Album (MvcMusicStore.Models)** from the **Model class** drop-down. Select **List** from the **Scaffold template** drop-down. Leave the **View engine** to **Razor** and the other fields with their default value and then click **Add**.

Adding an Index View

Task 4 - Customizing the scaffold of the Index View

In this task, you will adjust the simple View template created with ASP.NET MVC scaffolding feature to have it display the fields you want.

> **NOTE**
>
> The **scaffolding** support within ASP.NET MVC generates a simple View template which lists all fields in the Album model. **Scaffolding** provides a quick way to get started on a strongly typed view: rather than having to write the View template manually, scaffolding quickly generates a default template and then you can modify the generated code.

1. Review the code created. The generated list of fields will be part of the following HTML table that **Scaffolding** is using for displaying tabular data.

```
@model IEnumerable<MvcMusicStore.Models.Album>

@{
     ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>
     @Html.ActionLink("Create New", "Create")
</p>
<table>
     <tr>
          <th>
                @Html.DisplayNameFor(model => model.GenreId)
          </th>
          <th>
                @Html.DisplayNameFor(model => model.ArtistId)
          </th>
          <th>
                @Html.DisplayNameFor(model => model.Title)
          </th>
          <th>
                @Html.DisplayNameFor(model => model.Price)
          </th>
          <th>
                @Html.DisplayNameFor(model => model.AlbumArtUrl)
          </th>
          <th></th>
     </tr>

@foreach (var item in Model) {
     <tr>
          <td>
                @Html.DisplayFor(modelItem => item.GenreId)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.ArtistId)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Title)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Price)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.AlbumArtUrl)
          </td>
          <td>
                @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |
                @Html.ActionLink("Details", "Details", new { id=item.AlbumId }) |
                @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
          </td>
     </tr>
}

</table>
```

2. Replace the **<table>** code with the following code to display only the **Genre**, **Artist**, **Album Title**, and **Price** fields. This deletes the **AlbumId** and **Album Art URL** columns. Also, it changes GenreId and ArtistId columns to display their linked class properties of **Artist.Name** and **Genre.Name**, and removes the **Details** link.

```
<table>
    <tr>
      <th></th>
      <th>Genre</th>
      <th>Artist</th>
      <th>Title</th>
      <th>Price</th>
    </tr>

    @foreach (var item in Model) {
     <tr>
          <td>
                @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |

                @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Genre.Name)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Artist.Name)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Title)
          </td>
          <td>
                @Html.DisplayFor(modelItem => item.Price)
          </td>
     </tr>
    }
</table>
```

3. Change the following descriptions.

```
@model IEnumerable<MvcMusicStore.Models.Album>
@{
    ViewBag.Title = "Store Manager - All Albums";
}

<h2>Albums</h2>
```

Task 5 - Running the Application

In this task, you will test that the **StoreManager Index** View template displays a list of albums according to the design of the previous steps.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager** to verify that a list of albums is displayed, showing their **Title**, **Artist** and **Genre**.

Browsing the list of albums

Exercise 2: Adding an HTML Helper

The StoreManager Index page has one potential issue: Title and Artist Name properties can both be long enough to throw off the table formatting. In this exercise you will learn how to add a custom HTML helper to truncate that text.

In the following figure, you can see how the format is modified because of the length of the text when you use a small browser size.

Browsing the list of Albums with not truncated text

Task 1 - Extending the HTML Helper

In this task, you will add a new method **Truncate** to the **HTML** object exposed within ASP.NET MVC Views. To do this, you will implement an **extension method** to the built-in **System.Web.Mvc.HtmlHelper** class provided by ASP.NET MVC.

> **NOTE**
>
> To read more about **Extension Methods**, please visit this msdn article. https://msdn.microsoft.com/library/bb383977.aspx.

1. Open the **Begin** solution located at **Source/Ex2-AddingAnHTMLHelper/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open StoreManager's Index View. To do this, in the Solution Explorer expand the **Views** folder, then the **StoreManager** and open the **Index.cshtml** file.

3. Add the following code below the **@model** directive to define the **Truncate** helper method.

```
@model IEnumerable<MvcMusicStore.Models.Album>

@helper Truncate(string input, int length)
{
     if (input.Length <= length) {
          @input
     } else {
          @input.Substring(0, length)<text>...</text>
     }
}

@{
     ViewBag.Title = "Store Manager - All Albums";
}

<h2>Albums</h2>
```

Task 2 - Truncating Text in the Page

In this task, you will use the **Truncate** method to truncate the text in the View template.

1. Open StoreManager's Index View. To do this, in the Solution Explorer expand the **Views** folder, then the **StoreManager** and open the **Index.cshtml** file.

2. Replace the lines that show the **Artist Name** and Album's **Title**. To do this, replace the following lines.

```
<tr>
     <td>
          @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |

          @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
     </td>
     <td>
          @Html.DisplayFor(modelItem => item.Genre.Name)
     </td>
     <td>
          @Truncate(item.Artist.Name, 25)
     </td>
     <td>
          @Truncate(item.Title, 25)
     </td>
     <td>
          @Html.DisplayFor(modelItem => item.Price)
     </td>
</tr>
```

Task 3 - Running the Application

In this task, you will test that the **StoreManager Index** View template truncates the Album's Title and Artist Name.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager** to verify that long texts in the **Title** and **Artist** column are truncated.

Truncated Titles and Artist Names

Exercise 3: Creating the Edit View

In this exercise, you will learn how to create a form to allow store managers to edit an Album. They will browse the **/StoreManager/Edit/id** URL (**id** being the unique id of the album to edit), thus making an HTTP-GET call to the server.

The Controller Edit action method will retrieve the appropriate Album from the database, create a **StoreManagerViewModel** object to encapsulate it (along with a list of Artists and Genres), and then pass it off to a View template to render the HTML page back to the user. This page will contain a **<form>** element with textboxes and dropdowns for editing the Album properties.

Once the user updates the Album form values and clicks the **Save** button, the changes are submitted via an HTTP-POST call back to **/StoreManager/Edit/id**. Although the URL remains the same as in the last call, ASP.NET MVC identifies that this time it is an HTTP-POST and therefore executes a different Edit action method (one decorated with **[HttpPost]**).

Task 1 - Implementing the HTTP-GET Edit Action Method

In this task, you will implement the HTTP-GET version of the Edit action method to retrieve the appropriate Album from the database, as well as a list of all Genres and Artists. It will package this data up into the **StoreManagerViewModel** object defined in the last step, which will then be passed to a View template to render the response with.

1. Open the **Begin** solution located at **Source/Ex3-CreatingTheEditView/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open the **StoreManagerController** class. To do this, expand the **Controllers** folder and double-click **StoreManagerController.cs**.

3. Replace the **HTTP-GET Edit** action method with the following code to retrieve the appropriate **Album** as well as the **Genres** and **Artists** lists.

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex3 StoreManagerController HTTP-GET Edit action*)

```
public ActionResult Edit(int id)
{
    Album album = this.db.Albums.Find(id);

    if (album == null)
    {
         return this.HttpNotFound();
    }

    this.ViewBag.GenreId = new SelectList(this.db.Genres, "GenreId", "Name", album.GenreId);
    this.ViewBag.ArtistId = new SelectList(this.db.Artists, "ArtistId", "Name", album.ArtistId);

    return this.View(album);
}
```

> **NOTE**
>
> You are using **System.Web.Mvc SelectList** for Artists and Genres instead of the **System.Collections.Generic** List.
>
> **SelectList** is a cleaner way to populate HTML dropdowns and manage things like current selection. Instantiating and later setting up these ViewModel objects in the controller action will make the Edit form scenario cleaner.

Task 2 - Creating the Edit View

In this task, you will create an Edit View template that will later display the album properties.

1. Create the Edit View. To do this, right-click inside the **Edit** action method and select **Add View**.

2. In the Add View dialog, verify that the View Name is **Edit**. Check the **Create a strongly-typed view** checkbox and select **Album (MvcMusicStore.Models)** from the **View data class** drop-down. Select **Edit** from the **Scaffold template** drop-down. Leave the other fields with their default value and then click **Add**.

Adding an Edit view

Task 3 - Running the Application

In this task, you will test that the **StoreManager Edit** View page displays the properties' values for the album passed as parameter.

1. Press **F5** to run the Application.
2. The project starts in the Home page. Change the URL to **/StoreManager/Edit/1** to verify that the properties' values for the album passed are displayed.

Browsing Album's Edit view

Task 4 - Implementing drop-downs on the Album Editor Template

In this task, you will add drop-downs to the View template created in the last task, so that the user can select from a list of Artists and Genres.

1. Replace all the **Album** fieldset code with the following:

```
<fieldset>
     <legend>Album</legend>

     @Html.HiddenFor(model => model.AlbumId)

     <div class="editor-label">
          @Html.LabelFor(model => model.Title)
     </div>
     <div class="editor-field">
          @Html.EditorFor(model => model.Title)
          @Html.ValidationMessageFor(model => model.Title)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.Price)
     </div>
     <div class="editor-field">
          @Html.EditorFor(model => model.Price)
          @Html.ValidationMessageFor(model => model.Price)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.AlbumArtUrl)
     </div>
     <div class="editor-field">
          @Html.EditorFor(model => model.AlbumArtUrl)
          @Html.ValidationMessageFor(model => model.AlbumArtUrl)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.Artist)
     </div>
     <div class="editor-field">
          @Html.DropDownList("ArtistId", (SelectList) ViewData["Artists"])
          @Html.ValidationMessageFor(model => model.ArtistId)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.Genre)
     </div>
     <div class="editor-field">
          @Html.DropDownList("GenreId", (SelectList) ViewData["Genres"])
          @Html.ValidationMessageFor(model => model.GenreId)
     </div>

     <p>
          <input type="submit" value="Save" />
     </p>
</fieldset>
```

> **NOTE**
>
> An **Html.DropDownList** helper has been added to render drop-downs for choosing Artists and Genres. The parameters passed to **Html.DropDownList** are:
>
> 1. The name of the form field (**"ArtistId"**).
> 2. The **SelectList** of values for the drop-down.

Task 5 - Running the Application

In this task, you will test that the **StoreManager Edit** View page displays drop-downs instead of Artist and Genre ID text fields.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager/Edit/1** to verify that it displays drop-downs instead of Artist and Genre ID text fields.

Browsing Album's Edit view, this time with dropdowns

Task 6 - Implementing the HTTP-POST Edit action method

Now that the Edit View displays as expected, you need to implement the HTTP-POST Edit Action method to save the changes made to the Album.

1. Close the browser if needed, to return to the Visual Studio window. Open **StoreManagerController** from the **Controllers** folder.

2. Replace **HTTP-POST Edit** action method code with the following (note that the method that must be replaced is overloaded version that receives two parameters):

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex3 StoreManagerController HTTP-POST Edit action*)

```
[HttpPost]
public ActionResult Edit(Album album)
{
     if (ModelState.IsValid)
     {
          this.db.Entry(album).State = EntityState.Modified;
          this.db.SaveChanges();

          return this.RedirectToAction("Index");
     }

     this.ViewBag.GenreId = new SelectList(this.db.Genres, "GenreId", "Name", album.GenreId);
     this.ViewBag.ArtistId = new SelectList(this.db.Artists, "ArtistId", "Name", album.ArtistId);

     return this.View(album);
}
```

NOTE

This method will be executed when the user clicks the **Save** button of the View and performs an HTTP-POST of the form values back to the server to persist them in the database. The decorator **[HttpPost]** indicates that the method should be used for those HTTP-POST scenarios. The method takes an **Album** object. ASP.NET MVC will automatically create the Album object from the posted <form> values.

The method will perform these steps:

1. If model is valid:
   a. Update the album entry in the context to mark it as a modified object.
   b. Save the changes and redirect to the index view.
2. If the model is not valid, it will populate the ViewBag with the **GenreId** and **ArtistId**, then it will return the view with the received Album object to allow the user perform any required update.

Task 7 - Running the Application

In this task, you will test that the **StoreManager Edit** View page actually saves the updated Album data in the database.

1. Press **F5** to run the Application.
2. The project starts in the Home page. Change the URL to **/StoreManager/Edit/1**. Change the Album title to **Load** and click on **Save**. Verify that album's title actually changed in the list of albums.

Updating an Album

Exercise 4: Adding a Create View

Now that the **StoreManagerController** supports the **Edit** ability, in this exercise you will learn how to add a Create View template to let store managers add new Albums to the application.

Like you did with the Edit functionality, you will implement the Create scenario using two separate methods within the **StoreManagerController** class:

1. One action method will display an empty form when store managers first visit the **/StoreManager/Create** URL.
2. A second action method will handle the scenario where the store manager clicks the **Save** button within the form and submits the values back to the **/StoreManager/Create** URL as an HTTP-POST.

Task 1 - Implementing the HTTP-GET Create action method

In this task, you will implement the HTTP-GET version of the Create action method to retrieve a list of all Genres and Artists, package this data up into a **StoreManagerViewModel** object, which will then be passed to a View template.

1. Open the **Begin** solution located at **Source/Ex4-AddingACreateView/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open **StoreManagerController** class. To do this, expand the **Controllers** folder and double-click **StoreManagerController.cs**.

3. Replace the **Create** action method code with the following:

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex4 StoreManagerController HTTP-GET Create action*)

```
//
// GET: /StoreManager/Create

public ActionResult Create()
{
     this.ViewBag.GenreId = new SelectList(this.db.Genres, "GenreId", "Name");
     this.ViewBag.ArtistId = new SelectList(this.db.Artists, "ArtistId", "Name");

     return this.View();
}
```

Task 2 - Adding the Create View

In this task, you will add the Create View template that will display a new (empty) Album form.

1. Right-click inside the **Create** action method and select **Add View**. This will bring up the Add View dialog.

2. In the Add View dialog, verify that the View Name is **Create**. Select the **Create a strongly-typed view** option and select **Album (MvcMusicStore.Models)** from the **Model class** drop-down and **Create** from the **Scaffold template** drop-down. Leave the other fields with their default value and then click **Add**.

Adding the Create View

3. Update the **GenreId** and **ArtistId** fields to use a drop-down list as shown below:

```
...
<fieldset>
     <legend>Album</legend>

     <div class="editor-label">
          @Html.LabelFor(model => model.GenreId, "Genre")
     </div>
     <div class="editor-field">
          @Html.DropDownList("GenreId", String.Empty)
          @Html.ValidationMessageFor(model => model.GenreId)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.ArtistId, "Artist")
     </div>
     <div class="editor-field">
          @Html.DropDownList("ArtistId", String.Empty)
          @Html.ValidationMessageFor(model => model.ArtistId)
     </div>

     <div class="editor-label">
          @Html.LabelFor(model => model.Title)
     </div>
    ...
```

Task 3 - Running the Application

In this task, you will test that the **StoreManager Create** View page displays an empty Album form.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager/Create**. Verify that an empty form is displayed for filling the new Album properties.

Create View with an empty form

Task 4 - Implementing the HTTP-POST Create Action Method

In this task, you will implement the HTTP-POST version of the Create action method that will be invoked when a user clicks the **Save** button. The method should save the new album in the database.

1. Close the browser if needed, to return to the Visual Studio window. Open **StoreManagerController** class. To do this, expand the **Controllers** folder and double-click **StoreManagerController.cs**.

2. Replace **HTTP-POST Create** action method code with the following:

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex4 StoreManagerController HTTP-POST Create action*)

```
[HttpPost]
public ActionResult Create(Album album)
{
     if (ModelState.IsValid)
     {
          this.db.Albums.Add(album);
          this.db.SaveChanges();

          return this.RedirectToAction("Index");
     }

     this.ViewBag.GenreId = new SelectList(this.db.Genres, "GenreId", "Name", album.GenreId);
     this.ViewBag.ArtistId = new SelectList(this.db.Artists, "ArtistId", "Name", album.ArtistId);

     return this.View(album);
}
```

> **NOTE**
>
> The Create action is pretty similar to the previous Edit action method but instead of setting the object as modified, it is being added to the context.

Task 5 - Running the Application

In this task, you will test that the **StoreManager Create** View page lets you create a new Album and then redirects to the StoreManager Index View.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager/Create**. Fill all the form fields with data for a new Album, like the one in the following figure:

Creating an Album

3. Verify that you get redirected to the StoreManager Index View that includes the new Album just created.

New Album Created

Exercise 5: Handling Deletion

The ability to delete albums is not yet implemented. This is what this exercise will be about. Like before, you will implement the Delete scenario using two separate methods within the **StoreManagerController** class:

1. One action method will display a confirmation form
2. A second action method will handle the form submission

Task 1 - Implementing the HTTP-GET Delete Action Method

In this task, you will implement the HTTP-GET version of the Delete action method to retrieve the album's information.

1. Open the **Begin** solution located at **Source/Ex5-HandlingDeletion/Begin/** folder. Otherwise, you might

continue using the **End** solution obtained by completing the previous exercise.

a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
>
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open **StoreManagerController** class. To do this, expand the **Controllers** folder and double-click **StoreManagerController.cs**.

3. The Delete controller action is exactly the same as the previous Store Details controller action: it queries the **album** object from the database using the **id** provided in the URL and returns the appropriate **View**. To do this, replace the HTTP-GET **Delete** action method code with the following:

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex5 Handling Deletion HTTP-GET Delete action*)

```
//
// GET: /StoreManager/Delete/5

public ActionResult Delete(int id)
{
     Album album = this.db.Albums.Find(id);

     if (album == null)
     {
          return this.HttpNotFound();
     }

     return this.View(album);
}
```

4. Right-click inside the **Delete** action method and select **Add View**. This will bring up the Add View dialog.

5. In the Add View dialog, verify that the View name is **Delete**. Select the **Create a strongly-typed view** option and select **Album (MvcMusicStore.Models)** from the **Model class** drop-down. Select **Delete** from the **Scaffold template** drop-down. Leave the other fields with their default value and then click **Add**.

Adding a Delete View

6. The Delete template shows all the fields from the model. You will show only the album's title. To do this, replace the content of the view with the following code:

```
@model MvcMusicStore.Models.Album
@{
     ViewBag.Title = "Delete";
}
<h2>Delete Confirmation</h2>

<h3> Are you sure you want to delete the album title <strong>@Model.Title </strong> ? </h3>

@using (Html.BeginForm()) {
     <p>
          <input type="submit" value="Delete" /> |
          @Html.ActionLink("Back to List", "Index")
     </p>
}
```

Task 2 - Running the Application

In this task, you will test that the **StoreManager Delete** View page displays a confirmation deletion form.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager**. Select one album to delete by clicking **Delete** and verify that the new view is uploaded.

Deleting an Album

Task 3- Implementing the HTTP-POST Delete Action Method

In this task, you will implement the HTTP-POST version of the Delete action method that will be invoked when a user clicks the **Delete** button. The method should delete the album in the database.

1. Close the browser if needed, to return to the Visual Studio window. Open **StoreManagerController** class. To do this, expand the **Controllers** folder and double-click **StoreManagerController.cs**.

2. Replace **HTTP-POST Delete** action method code with the following:

   (Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex5 Handling Deletion HTTP-POST Delete action*)

```
//
// POST: /StoreManager/Delete/5

[HttpPost]
public ActionResult Delete(int id, FormCollection collection)
{
     Album album = this.db.Albums.Find(id);
     this.db.Albums.Remove(album);
     this.db.SaveChanges();

     return this.RedirectToAction("Index");
}
```

Task 4 - Running the Application

In this task, you will test that the **StoreManager Delete** View page lets you delete an Album and then redirects to the StoreManager Index View.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager**. Select one album to delete by clicking **Delete.** Confirm the deletion by clicking **Delete** button:

Deleting an Album

3. Verify that the album was deleted since it does not appear in the **Index** page.

Exercise 6: Adding Validation

Currently, the Create and Edit forms you have in place do not perform any kind of validation. If the user leaves a required field blank or type letters in the price field, the first error you will get will be from the database.

You can add validation to the application by adding Data Annotations to your model class. Data Annotations allow describing the rules you want applied to your model properties, and ASP.NET MVC will take care of enforcing and displaying appropriate message to users.

Task 1 - Adding Data Annotations

In this task, you will add Data Annotations to the Album Model that will make the Create and Edit page display validation messages when appropriate.

For a simple Model class, adding a Data Annotation is just handled by adding a **using** statement for **System.ComponentModel.DataAnnotation**, then placing a **[Required]** attribute on the appropriate properties. The following example would make the **Name** property a required field in the View.

```
using System.ComponentModel.DataAnnotations;
namespace SuperheroSample.Models
{
    public class Superhero
    {
        [Required]
        public string Name { get; set; }

        public bool WearsCape { get; set; }
    }
}
```

This is a little more complex in cases like this application where the Entity Data Model is generated. If you added Data Annotations directly to the model classes, they would be overwritten if you update the model from the database. Instead, you can make use of metadata partial classes which will exist to hold the annotations and are associated with the model classes using the **[MetadataType]** attribute.

1. Open the **Begin** solution located at **Source/Ex6-AddingValidation/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

c. Finally, build the solution by clicking **Build | Build Solution**.

> **NOTE**
> One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Open the **Album.cs** from the **Models** folder.

3. Replace **Album.cs** content with the highlighted code, so that it looks like the following:

> **NOTE**
> The line **[DisplayFormat(ConvertEmptyStringToNull=false)]** indicates that empty strings from the model won't be converted to null when the data field is updated in the data source. This setting will avoid an exception when the Entity Framework assigns null values to the model before Data Annotation validates the fields.

(Code Snippet - *ASP.NET MVC 4 Helpers and Forms and Validation - Ex6 Album metadata partial class*)

```
namespace MvcMusicStore.Models
{
    using System.ComponentModel;
    using System.ComponentModel.DataAnnotations;

    public class Album
    {
        [ScaffoldColumn(false)]
        public int AlbumId { get; set; }

        [DisplayName("Genre")]
        public int GenreId { get; set; }

        [DisplayName("Artist")]
        public int ArtistId { get; set; }

        [Required(ErrorMessage = "An Album Title is required")]
        [DisplayFormat(ConvertEmptyStringToNull = false)]
        [StringLength(160, MinimumLength = 2)]
        public string Title { get; set; }

        [Range(0.01, 100.00, ErrorMessage = "Price must be between 0.01 and 100.00")]
        [DataType(DataType.Currency)]
        public decimal Price { get; set; }

        [DisplayName("Album Art URL")]
        [DataType(DataType.ImageUrl)]
        [StringLength(1024)]
        public string AlbumArtUrl { get; set; }

        public virtual Genre Genre { get; set; }

        public virtual Artist Artist { get; set; }
    }
}
```

> **NOTE**
>
> This **Album** partial class has a **MetadataType** attribute which points to the **AlbumMetaData** class for the Data Annotations. These are some of the Data Annotation attributes you are using to annotate the Album model:
>
> - Required - Indicates that the property is a required field
> - DisplayName - Defines the text to be used on form fields and validation messages
> - DisplayFormat - Specifies how data fields are displayed and formatted.
> - StringLength - Defines a maximum length for a string field
> - Range - Gives a maximum and minimum value for a numeric field
> - ScaffoldColumn - Allows hiding fields from editor forms

Task 2 - Running the Application

In this task, you will test that the Create and Edit pages validate fields, using the display names chosen in the last task.

1. Press **F5** to run the Application.

2. The project starts in the Home page. Change the URL to **/StoreManager/Create**. Verify that the display names match the ones in the partial class (like **Album Art URL** instead of **AlbumArtUrl**)

3. Click **Create**, without filling the form. Verify that you get the corresponding validation messages.

Validated fields in the Create page

4. You can verify that the same occurs with the **Edit** page. Change the URL to **/StoreManager/Edit/1** and verify that the display names match the ones in the partial class (like **Album Art URL** instead of **AlbumArtUrl**). Empty the **Title** and **Price** fields and click **Save**. Verify that you get the corresponding validation messages.

Validated fields in the Edit page

Exercise 7: Using Unobtrusive jQuery at Client Side

In this exercise, you will learn how to enable MVC 4 Unobtrusive jQuery validation at client side.

> **NOTE**
> The Unobtrusive jQuery uses data-ajax prefix JavaScript to invoke action methods on the server rather than intrusively emitting inline client scripts.

Task 1 - Running the Application before Enabling Unobtrusive jQuery

In this task, you will run the application before including jQuery in order to compare both validation models.

1. Open the **Begin** solution located at **Source/Ex7-UnobtrusivejQueryValidation/Begin/** folder. Otherwise, you might continue using the **End** solution obtained by completing the previous exercise.

   a. If you opened the provided **Begin** solution, you will need to download some missing NuGet packages before continue. To do this, click the **Project** menu and select **Manage NuGet Packages**.

   b. In the **Manage NuGet Packages** dialog, click **Restore** in order to download missing packages.

   c. Finally, build the solution by clicking **Build | Build Solution**.

   > **NOTE**
   > One of the advantages of using NuGet is that you don't have to ship all the libraries in your project, reducing the project size. With NuGet Power Tools, by specifying the package versions in the Packages.config file, you will be able to download all the required libraries the first time you run the project. This is why you will have to run these steps after you open an existing solution from this lab.

2. Press **F5** to run the application.

3. The project starts in the Home page. Browse **/StoreManager/Create** and click **Create** without filling the form to verify that you get validation messages:

Client validation disabled

4. In the browser, open the HTML source code:

```
...
          <div class="editor-label">
                <label for="Price">Price</label>
          </div>
          <div class="editor-field">
                <input class="text-box single-line" id="Price" name="Price" type="text" value="" />
                <span class="field-validation-valid" id="Price_validationMessage"></span>
          </div>

          <div class="editor-label">
                <label for="AlbumArtUrl">Album Art URL</label>
          </div>
          <div class="editor-field">
                <input class="text-box single-line" id="AlbumArtUrl" name="AlbumArtUrl" type="text"
value="" />
                <span class="field-validation-valid" id="AlbumArtUrl_validationMessage"></span>
          </div>

          <p>
                <input type="submit" value="Create" />
          </p>
     </fieldset>
</form><script type="text/javascript">
//<![CDATA[
if (!window.mvcClientValidationMetadata) { window.mvcClientValidationMetadata = []; }
window.mvcClientValidationMetadata.push({"Fields":
[{"FieldName":"GenreId","ReplaceValidationMessageContents":true,"ValidationMessageId":"GenreId_validati
onMessage","ValidationRules":[{"ErrorMessage":"The Genre field is required.","ValidationParameters":
{},"ValidationType":"required"},{"ErrorMessage":"The field Genre must be a
number.","ValidationParameters":{},"ValidationType":"number"}]},
{"FieldName":"ArtistId","ReplaceValidationMessageContents":true,"ValidationMessageId":"ArtistId_validat
ionMessage","ValidationRules":[{"ErrorMessage":"The Artist field is required.","ValidationParameters":
{},"ValidationType":"required"},{"ErrorMessage":"The field Artist must be a
number.","ValidationParameters":{},"ValidationType":"number"}]},
{"FieldName":"Title","ReplaceValidationMessageContents":true,"ValidationMessageId":"Title_validationMes
sage","ValidationRules":[{"ErrorMessage":"An Album Title is required","ValidationParameters":
{},"ValidationType":"required"},{"ErrorMessage":"The field Title must be a string with a minimum length
of 2 and a maximum length of 160.","ValidationParameters":
{"min":2,"max":160},"ValidationType":"length"}]},
{"FieldName":"Price","ReplaceValidationMessageContents":true,"ValidationMessageId":"Price_validationMes
sage","ValidationRules":[{"ErrorMessage":"Price must be between 0.01 and
100.00","ValidationParameters":{"min":0.01,"max":100},"ValidationType":"range"},{"ErrorMessage":"Price
is required","ValidationParameters":{},"ValidationType":"required"},{"ErrorMessage":"The field Price
must be a number.","ValidationParameters":{},"ValidationType":"number"}]},
{"FieldName":"AlbumArtUrl","ReplaceValidationMessageContents":true,"ValidationMessageId":"AlbumArtUrl_v
alidationMessage","ValidationRules":[{"ErrorMessage":"The field Album Art URL must be a string with a
maximum length of 1024.","ValidationParameters":
{"max":1024},"ValidationType":"length"}]}],"FormId":"form0","ReplaceValidationSummary":false,"Validatio
nSummaryId":"validationSummary"});
//]]>
</script>
...
```

Task 2 - Enabling Unobtrusive Client Validation

In this task, you will enable jQuery **unobtrusive client validation** from **Web.config** file, which is by default set to false in all new ASP.NET MVC 4 projects. Additionally, you will add the necessary scripts references to make jQuery Unobtrusive Client Validation work.

1. Open **Web.Config** file at project root, and make sure that the **ClientValidationEnabled** and **UnobtrusiveJavaScriptEnabled** keys values are set to **true**.

```
...
<configuration>
  <appSettings>
     <add key="webpages:Version" value="2.0.0.0" />
     <add key="webpages:Enabled" value="false" />
     <add key="PreserveLoginUrl" value="true" />
     <add key="ClientValidationEnabled" value="true" />
     <add key="UnobtrusiveJavaScriptEnabled" value="true" />
</appSettings>
...
```

> **NOTE**
>
> You can also enable client validation by code at Global.asax.cs to get the same results:
>
> **HtmlHelper.ClientValidationEnabled = true;**
>
> Additionally, you can assign ClientValidationEnabled attribute into any controller to have a custom behavior.

2. Open **Create.cshtml** at **Views\StoreManager**.

3. Make sure the following script files, **jquery.validate** and **jquery.validate.unobtrusive**, are referenced in the view through the "**~/bundles/jqueryval**" bundle.

```
...
@section Scripts {
     @Scripts.Render("~/bundles/jqueryval")
}
```

> **NOTE**
>
> All these jQuery libraries are included in MVC 4 new projects. You can find more libraries in the **/Scripts** folder of you project.
>
> In order to make this validation libraries work, you need to add a reference to the jQuery framework library. Since this reference is already added in the **_Layout.cshtml** file, you do not need to add it in this particular view.

Task 3 - Running the Application Using Unobtrusive jQuery Validation

In this task, you will test that the **StoreManager** create view template performs client side validation using jQuery libraries when the user creates a new album.

1. Press **F5** to run the application.

2. The project starts in the Home page. Browse **/StoreManager/Create** and click **Create** without filling the form to verify that you get validation messages:

Client validation with jQuery enabled

3. In the browser, open the source code for Create view:

```
...
<div class="editor-label">
    <label for="Title">Title</label>
</div>
<div class="editor-field">
    <input class="text-box single-line" data-val="true" data-val-length="The field Title must be a
string with a minimum length of 2 and a maximum length of 160." data-val-length-max="160" data-val-
length-min="2" data-val-required="An Album Title is required" id="Title" name="Title" type="text"
value="" />
    <span class="field-validation-valid" data-valmsg-for="Title" data-valmsg-replace="true"></span>
</div>

<div class="editor-label">
    <label for="Price">Price</label>
</div>
<div class="editor-field">
    <input class="text-box single-line" data-val="true" data-val-number="The field Price must be a
number." data-val-range="Price must be between 0.01 and 100.00" data-val-range-max="100" data-val-
range-min="0.01" data-val-required="Price is required" id="Price" name="Price" type="text" value="" />
    <span class="field-validation-valid" data-valmsg-for="Price" data-valmsg-replace="true"></span>
</div>

<div class="editor-label">
    <label for="AlbumArtUrl">Album Art URL</label>
</div>
<div class="editor-field">
    <input class="text-box single-line" data-val="true" data-val-length="The field Album Art URL must
be a string with a maximum length of 1024." data-val-length-max="1024" id="AlbumArtUrl"
name="AlbumArtUrl" type="text" value="" />
    <span class="field-validation-valid" data-valmsg-for="AlbumArtUrl" data-valmsg-replace="true">
</span>
</div>
...
```

NOTE

For each client validation rule, Unobtrusive jQuery adds an attribute with data-val-*rulename*="*message*". Below is a list of tags that Unobtrusive jQuery inserts into the html input field to perform client validation:

- Data-val
- Data-val-number
- Data-val-range
- Data-val-range-min / Data-val-range-max
- Data-val-required
- Data-val-length
- Data-val-length-max / Data-val-length-min

All the data values are filled with model **Data Annotation**. Then, all the logic that works at server side can be run at client side. For example, Price attribute has the following data annotation in the model:

```
[Required(ErrorMessage = "Price is required")]
[Range(0.01, 100.00, ErrorMessage = "Price must be between 0.01 and 100.00")]
public object Price { get; set; }
```

After using Unobtrusive jQuery, the generated code is:

```
<input data-val="true"
data-val-number="The field Price must be a number."
data-val-range="Price must be between 0.01 and 100.00"
data-val-range-max="100"
data-val-range-min="0.01"
data-val-required="Price is required"
id="Album_Price" name="Album.Price" type="text" value="0" />
```

Summary

By completing this Hands-On Lab you have learned how to enable users to change the data stored in the database with the use of the following:

- Controller actions like Index, Create, Edit, Delete
- ASP.NET MVC's scaffolding feature for displaying properties in an HTML table
- Custom HTML helpers to improve user experience
- Action methods that react to either HTTP-GET or HTTP-POST calls
- A shared editor template for similar View templates like Create and Edit
- Form elements like drop-downs
- Data annotations for Model validation
- Client Side Validation using jQuery Unobtrusive library

Appendix A: Installing Visual Studio Express 2012 for Web

You can install **Microsoft Visual Studio Express 2012 for Web** or another "Express" version using the **Microsoft Web Platform Installer**. The following instructions guide you through the steps required to install *Visual studio Express 2012 for Web* using *Microsoft Web Platform Installer*.

1. Go to https://go.microsoft.com/?linkid=9810169. Alternatively, if you already have installed Web Platform Installer, you can open it and search for the product "*Visual Studio Express 2012 for Web with Windows Azure SDK*".

2. Click on **Install Now**. If you do not have **Web Platform Installer** you will be redirected to download and

install it first.

3. Once **Web Platform Installer** is open, click **Install** to start the setup.

Install Visual Studio Express

4. Read all the products' licenses and terms and click **I Accept** to continue.

Accepting the license terms

5. Wait until the downloading and installation process completes.

Installation progress

6. When the installation completes, click **Finish**.

Installation completed

7. Click **Exit** to close Web Platform Installer.

8. To open Visual Studio Express for Web, go to the **Start** screen and start writing "**VS Express**", then click on the **VS Express for Web** tile.

VS Express for Web tile

Appendix B: Using Code Snippets

With code snippets, you have all the code you need at your fingertips. The lab document will tell you exactly when you can use them, as shown in the following figure.

6. Insert the following code inside the body of the **Run** method.

(Code Snippet – *AzurePlatformTrainingKit - Ex1-Task 1 -Step 5- Run method*)

C#

```
public override void Run()
{
  while (true)
  {
    // retrieve a new message from the queue
    CloudQueueMessage message = queue.GetMessage();
    if (message != null)
    {
      ProcessMessage(message);
      queue.DeleteMessage(msg);
    }
  }
}
```

Using Visual Studio code snippets to insert code into your project

To add a code snippet using the keyboard (C# only)

1. Place the cursor where you would like to insert the code.
2. Start typing the snippet name (without spaces or hyphens).
3. Watch as IntelliSense displays matching snippets' names.
4. Select the correct snippet (or keep typing until the entire snippet's name is selected).
5. Press the Tab key twice to insert the snippet at the cursor location.

Start typing the snippet name

```
static void Main(string[] args)
{
    AzureTrainingKitServiceBus
}
```

Press Tab to select the highlighted snippet

```
static void Main(string[] args)
{
    request.Headers.Add("$accountKey", accountKey);
    request.Headers.Add("$uniqueUserID", uniqueUserId);
}
```

Press Tab again and the snippet will expand

To add a code snippet using the mouse (C#, Visual Basic and XML) 1. Right-click where you want to insert the code snippet.

1. Select **Insert Snippet** followed by **My Code Snippets**.
2. Pick the relevant snippet from the list, by clicking on it.

Right-click where you want to insert the code snippet and select Insert Snippet

Pick the relevant snippet from the list, by clicking on it

ASP.NET MVC 4 Mobile Features

2/20/2020 • 17 minutes to read • Edit Online

by Rick Anderson

> There is now an MVC 5 version of this tutorial with code samples at Deploy an ASP.NET MVC 5 Mobile Web Application on Azure Web Sites.

This tutorial will teach you the basics of how to work with mobile features in an ASP.NET MVC 4 Web application. For this tutorial, you can use Visual Studio Express 2012 or Visual Web Developer 2010 Express Service Pack 1 ("Visual Web Developer or VWD"). You can use the professional version of Visual Studio if you already have that.

Before you start, make sure you've installed the prerequisites listed below.

- Visual Studio Express 2012 (recommended) or Visual Studio Web Developer Express SP1. Visual Studio 2012 contains ASP.NET MVC 4. If you are using Visual Web Developer 2010, you must install ASP.NET MVC 4.

You will also need a mobile browser emulator. Any of the following will work:

- Windows 7 Phone Emulator. (This is the emulator that's used in most of the screen shots in this tutorial.)
- Change the user agent string to emulate an iPhone. See this blog entry.
- Opera Mobile Emulator
- Apple Safari with the user agent set to iPhone. For instructions on how to set the user agent in Safari to "iPhone", see How to let Safari pretend it's IE on David Alison's blog.

Visual Studio projects with C# source code are available to accompany this topic:

- Starter project download
- Completed project download

What You'll Build

For this tutorial, you'll add mobile features to the simple conference-listing application that's provided in the starter project. The following screenshot shows the tags page of the completed application as seen in the Windows 7 Phone Emulator. See Keyboard Mapping for Windows Phone Emulator to simplify keyboard input.

You can use Internet Explorer version 9 or 10, FireFox or Chrome to develop your mobile application by setting the user agent string. The following image shows the completed tutorial using Internet Explorer emulating an iPhone. You can use the Internet Explorer F-12 developer tools and the Fiddler tool to help debug your application.

Skills You'll Learn

Here's what you'll learn:

- How the ASP.NET MVC 4 templates use the HTML5 `viewport` attribute and adaptive rendering to improve display on mobile devices.
- How to create mobile-specific views.

- How to create a view switcher that lets users toggle between a mobile view and a desktop view of the application.

Getting Started

Download the conference-listing application for the starter project using the following link: Download. Then in Windows Explorer, right-click the *MvcMobile.zip* file and choose **Properties**. In the **MvcMobile.zip Properties** dialog box, choose the **Unblock** button. (Unblocking prevents a security warning that occurs when you try to use a *.zip* file that you've downloaded from the web.)

Right-click the *MvcMobile.zip* file and select **Extract All** to unzip the file. In Visual Studio, open the *MvcMobile.sln* file.

Press CTRL+F5 to run the application, which will display it in your desktop browser. Start your mobile browser emulator, copy the URL for the conference application into the emulator, and then click the **Browse by tag** link. If you are using the Windows Phone Emulator, click in the URL bar and press the Pause key to get keyboard access. The image below shows the *AllTags* view (from choosing **Browse by tag**).

The display is very readable on a mobile device. Choose the ASP.NET link.

The ASP.NET tag view is very cluttered. For example, the **Date** column is very difficult to read. Later in the tutorial you'll create a version of the *AllTags* view that's specifically for mobile browsers and that will make the display readable.

Note: Currently a bug exists in the mobile caching engine. For production applications, you must install the Fixed DisplayModes nugget package. See ASP.NET MVC 4 Mobile Caching Bug Fixed for details on the fix.

CSS Media Queries

CSS media queries are an extension to CSS for media types. They allow you to create rules that override the default CSS rules for specific browsers (user agents). A common rule for CSS that targets mobile browsers is defining the maximum screen size. The *Content\Site.css* file that's created when you create a new ASP.NET MVC 4 Internet project contains the following media query:

```
@media only screen and (max-width: 850px) {
```

If the browser window is 850 pixels wide or less, it will use the CSS rules inside this media block. You can use CSS media queries like this to provide a better display of HTML content on small browsers (like mobile browsers) than the default CSS rules that are designed for the wider displays of desktop browsers.

The Viewport Meta Tag

Most mobile browsers define a virtual browser window width (the *viewport*) that's much larger than the actual width of the mobile device. This allows mobile browsers to fit the entire web page inside the virtual display. Users can then zoom in on interesting content. However, if you set the viewport width to the actual device width, no zooming is required, because the content fits in the mobile browser.

The viewport `<meta>` tag in the ASP.NET MVC 4 layout file sets the viewport to the device width. The following line shows the viewport `<meta>` tag in the ASP.NET MVC 4 layout file.

```
<meta name="viewport" content="width=device-width">
```

Examining the Effect of CSS Media Queries and the Viewport Meta Tag

Open the *Views\Shared_Layout.cshtml* file in the editor and comment out the viewport `<meta>` tag. The following markup shows the commented-out line.

```
@*<meta name="viewport" content="width=device-width">*@
```

Open the *MvcMobile\Content\Site.css* file in the editor and change the maximum width in the media query to zero pixels. This will prevent the CSS rules from being used in mobile browsers. The following line shows the modified media query:

```
@media only screen and (max-width: 0px) { ...
```

Save your changes and browse to the Conference application in a mobile browser emulator. The tiny text in the following image is the result of removing the viewport `<meta>` tag. With no viewport `<meta>` tag, the browser is zooming out to the default viewport width (850 pixels or wider for most mobile browsers.)

Undo your changes — uncomment the viewport `<meta>` tag in the layout file and restore the media query to 850 pixels in the *Site.css* file. Save your changes and refresh the mobile browser to verify that the mobile-friendly display has been restored.

The viewport `<meta>` tag and the CSS media query are not specific to ASP.NET MVC 4, and you can take advantage of these features in any web application. But they are now built into the files that are generated when you create a new ASP.NET MVC 4 project.

For more information about the viewport `<meta>` tag, see A tale of two viewports — part two.

In the next section you'll see how to provide mobile-browser specific views.

Overriding Views, Layouts, and Partial Views

A significant new feature in ASP.NET MVC 4 is a simple mechanism that lets you override any view (including layouts and partial views) for mobile browsers in general, for an individual mobile browser, or for any specific browser. To provide a mobile-specific view, you can copy a view file and add *.Mobile* to the file name. For example, to create a mobile *Index* view, copy *Views\Home\Index.cshtml* to *Views\Home\Index.Mobile.cshtml*.

In this section, you'll create a mobile-specific layout file.

To start, copy *Views\Shared_Layout.cshtml* to *Views\Shared_Layout.Mobile.cshtml*. Open *_Layout.Mobile.cshtml* and change the title from **MVC4 Conference** to **Conference (Mobile)**.

In each `Html.ActionLink` call, remove "Browse by" in each link *ActionLink*. The following code shows the completed body section of the mobile layout file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width" />
    <title>@ViewBag.Title</title>
    @Styles.Render("~/Content/css")
    @Scripts.Render("~/bundles/modernizr")
</head>
<body>
    <div id="title">
        <h1> Conference (Mobile)</h1>
    </div>
    <div id="menucontainer">
        <ul id="menu">
            <li>@Html.ActionLink("Home", "Index", "Home")</li>
            <li>@Html.ActionLink("Date", "AllDates", "Home")</li>
            <li>@Html.ActionLink("Speaker", "AllSpeakers", "Home")</li>
            <li>@Html.ActionLink("Tag", "AllTags", "Home")</li>
        </ul>
    </div>
    @RenderBody()

    @Scripts.Render("~/bundles/jquery")
    @RenderSection("scripts", required: false)
</body>
</html>
```

Copy the *Views\Home\AllTags.cshtml* file to *Views\Home\AllTags.Mobile.cshtml*. Open the new file and change the `<h2>` element from "Tags" to "Tags (M)":

```
<h2>Tags (M)</h2>
```

Browse to the tags page using a desktop browser and using mobile browser emulator. The mobile browser emulator shows the two changes you made.

In contrast, the desktop display has not changed.

Browser-Specific Views

In addition to mobile-specific and desktop-specific views, you can create views for an individual browser. For example, you can create views that are specifically for the iPhone browser. In this section, you'll create a layout for the iPhone browser and an iPhone version of the *AllTags* view.

Open the *Global.asax* file and add the following code to the `Application_Start` method.

```
DisplayModeProvider.Instance.Modes.Insert(0, new DefaultDisplayMode("iPhone")
{
    ContextCondition = (context => context.GetOverriddenUserAgent().IndexOf
        ("iPhone", StringComparison.OrdinalIgnoreCase) >= 0)
});
```

This code defines a new display mode named "iPhone" that will be matched against each incoming request. If the incoming request matches the condition you defined (that is, if the user agent contains the string "iPhone"), ASP.NET MVC will look for views whose name contains the "iPhone" suffix.

In the code, right-click `DefaultDisplayMode`, choose **Resolve**, and then choose `using System.Web.WebPages;`. This adds a reference to the `System.Web.WebPages` namespace, which is where the `DisplayModes` and `DefaultDisplayMode` types are defined.

Alternatively, you can just manually add the following line to the `using` section of the file.

```
using System.Web.WebPages;
```

The complete contents of the *Global.asax* file is shown below.

```
using System;
using System.Web.Http;
using System.Web.Mvc;
using System.Web.Optimization;
using System.Web.Routing;
using System.Web.WebPages;

namespace MvcMobile
{

    public class MvcApplication : System.Web.HttpApplication
    {
        protected void Application_Start()
        {
            DisplayModeProvider.Instance.Modes.Insert(0, new DefaultDisplayMode("iPhone")
            {
                ContextCondition = (context => context.GetOverriddenUserAgent().IndexOf
                    ("iPhone", StringComparison.OrdinalIgnoreCase) >= 0)
            });

            AreaRegistration.RegisterAllAreas();

            WebApiConfig.Register(GlobalConfiguration.Configuration);
            FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
            RouteConfig.RegisterRoutes(RouteTable.Routes);
            BundleConfig.RegisterBundles(BundleTable.Bundles);
        }
    }
}
```

Save the changes. Copy the *MvcMobile\Views\Shared_Layout.Mobile.cshtml* file to *MvcMobile\Views\Shared_Layout.iPhone.cshtml*. Open the new file and then change the `h1` heading from `Conference (Mobile)` to `Conference (iPhone)`.

Copy the *MvcMobile\Views\Home\AllTags.Mobile.cshtml* file to *MvcMobile\Views\Home\AllTags.iPhone.cshtml*. In the new file, change the `<h2>` element from "Tags (M)" to "Tags (iPhone)".

Run the application. Run a mobile browser emulator, make sure its user agent is set to "iPhone", and browse to the *AllTags* view. The following screenshot shows the *AllTags* view rendered in the Safari browser. You can download Safari for Windows here.

In this section we've seen how to create mobile layouts and views and how to create layouts and views for specific devices such as the iPhone. In the next section you'll see how to leverage jQuery Mobile for more compelling mobile views.

Using jQuery Mobile

The jQuery Mobile library provides a user interface framework that works on all the major mobile browsers. jQuery Mobile applies *progressive enhancement* to mobile browsers that support CSS and JavaScript. Progressive enhancement allows all browsers to display the basic content of a web page, while allowing more powerful browsers and devices to have a richer display. The JavaScript and CSS files that are included with jQuery Mobile style many elements to fit mobile browsers without making any markup changes.

In this section you'll install the *jQuery.Mobile.MVC* NuGet package, which installs jQuery Mobile and a view-switcher widget.

To start, delete the *Shared_Layout.Mobile.cshtml* and *Shared_Layout.iPhone.cshtml* files that you created earlier.

Rename *Views\Home\AllTags.Mobile.cshtml* and *Views\Home\AllTags.iPhone.cshtml* files to *Views\Home\AllTags.iPhone.cshtml.hide* and *Views\Home\AllTags.Mobile.cshtml.hide*. Because the files no longer have a *.cshtml* extension, they won't be used by the ASP.NET MVC runtime to render the *AllTags* view.

Install the *jQuery.Mobile.MVC* NuGet package by doing this:

1. From the **Tools** menu, select **NuGet Package Manager**, and then select **Package Manager Console**.

2. In the **Package Manager Console**, enter `Install-Package jQuery.Mobile.MVC -version 1.0.0`

The following image shows the files added and changed to the MvcMobile project by the NuGet jQuery.Mobile.MVC package. Files which are added have [add] appended after the file name. The image does not show the GIF and PNG files added to the *Content\images* folder.

The jQuery.Mobile.MVC NuGet package installs the following:

- The *App_Start\BundleMobileConfig.cs* file, which is needed to reference the jQuery JavaScript and CSS files added. You must follow the instructions below and reference the mobile bundle defined in this file.

- jQuery Mobile CSS files.
- A `ViewSwitcher` controller widget (*Controllers\ViewSwitcherController.cs*).
- jQuery Mobile JavaScript files.
- A jQuery Mobile-styled layout file (*Views\Shared_Layout.Mobile.cshtml*).
- A view-switcher partial view *(MvcMobile\Views\Shared_ViewSwitcher.cshtml*) that provides a link at the top of each page to switch from desktop view to mobile view and vice versa.
- Several *.png* and *.gif* image files in the *Content\images* folder.

Open the *Global.asax* file and add the following code as the last line of the `Application_Start` method.

```
BundleMobileConfig.RegisterBundles(BundleTable.Bundles);
```

The following code shows the complete *Global.asax* file.

```
using System;
using System.Web.Http;
using System.Web.Mvc;
using System.Web.Optimization;
using System.Web.Routing;
using System.Web.WebPages;

namespace MvcMobile
{

    public class MvcApplication : System.Web.HttpApplication
    {
        protected void Application_Start()
        {
            DisplayModeProvider.Instance.Modes.Insert(0, new DefaultDisplayMode("iPhone")
            {
                ContextCondition = (context => context.GetOverriddenUserAgent().IndexOf
                    ("iPhone", StringComparison.OrdinalIgnoreCase) >= 0)
            });
            AreaRegistration.RegisterAllAreas();

            WebApiConfig.Register(GlobalConfiguration.Configuration);
            FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
            RouteConfig.RegisterRoutes(RouteTable.Routes);
            BundleConfig.RegisterBundles(BundleTable.Bundles);
            BundleMobileConfig.RegisterBundles(BundleTable.Bundles);
        }
    }
}
```

NOTE

If you are using Internet Explorer 9 and you don't see the `BundleMobileConfig` line above in yellow highlight, click the Compatibility View button![Picture of the Compatibility View button (off)](https://res2.windows.microsoft.com/resbox/en/Windows 7/main/f080e77f-9b66-4ac8-9af0-803c4f8a859c_15.jpg "Picture of the Compatibility View button (off)") in IE to make the icon change from an outline ![Picture of the Compatibility View button (off)](https://res2.windows.microsoft.com/resbox/en/Windows 7/main/f080e77f-9b66-4ac8-9af0-803c4f8a859c_15.jpg "Picture of the Compatibility View button (off)") to a solid color ![Picture of the Compatibility View button (on)](https://res1.windows.microsoft.com/resbox/en/Windows 7/main/156805ff-3130-481b-a12d-4d3a96470f36_14.jpg "Picture of the Compatibility View button (on)"). Alternatively you can view this tutorial in FireFox or Chrome.

Open the *MvcMobile\Views\Shared_Layout.Mobile.cshtml* file and add the following markup directly after the

`Html.Partial` call:

```
<div data-role="header" align="center">
    @Html.ActionLink("Home", "Index", "Home")
    @Html.ActionLink("Date", "AllDates")
    @Html.ActionLink("Speaker", "AllSpeakers")
    @Html.ActionLink("Tag", "AllTags")
</div>
```

The complete *MvcMobile\Views\Shared_Layout.Mobile.cshtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>@ViewBag.Title</title>
    <meta name="viewport" content="width=device-width" />
    @Styles.Render("~/Content/Mobile/css", "~/Content/jquerymobile/css")
    @Scripts.Render("~/bundles/jquery", "~/bundles/jquerymobile")
</head>
<body>

    <div data-role="page" data-theme="a">
        @Html.Partial("_ViewSwitcher")
        <div data-role="header" align="center">
            @Html.ActionLink("Home", "Index", "Home")
            @Html.ActionLink("Date", "AllDates")
            @Html.ActionLink("Speaker", "AllSpeakers")
            @Html.ActionLink("Tag", "AllTags")
        </div>
        <div data-role="header">
            <h1>@ViewBag.Title</h1>
        </div>

        <div data-role="content">
            @RenderSection("featured", false)
            @RenderBody()
        </div>

    </div>

</body>
</html>
```

Build the application, and in your mobile browser emulator browse to the *AllTags* view. You see the following:

NOTE

You can debug the mobile specific code by setting the user agent string for IE or Chrome to iPhone and then using the F-12 developer tools. If your mobile browser doesn't display the **Home**, **Speaker**, **Tag**, and **Date** links as buttons, the references to jQuery Mobile scripts and CSS files are probably not correct.

In addition to the style changes, you see **Displaying mobile view** and a link that lets you switch from mobile view to desktop view. Choose the **Desktop view** link, and the desktop view is displayed.

The desktop view doesn't provide a way to directly navigate back to the mobile view. You'll fix that now. Open the *Views\Shared_Layout.cshtml* file. Just under the page `body` element, add the following code, which renders the view-switcher widget:

```
@Html.Partial("_ViewSwitcher")
```

Refresh the *AllTags* view in the mobile browser. You can now navigate between desktop and mobile views.

NOTE

Debug note: You can add the following code to the end of the Views\Shared_ViewSwitcher.cshtml to help debug views when using a browser the user agent string set to a mobile device.

```
else
{
     @:Not Mobile/Get
}
```

and adding the following heading to the *Views\Shared_Layout.cshtml* file.

```
<h1> Non Mobile Layout MVC4 Conference </h1>
```

Browse to the *AllTags* page in a desktop browser. The view-switcher widget is not displayed in a desktop browser because it's added only to the mobile layout page. Later in the tutorial you'll see how you can add the view-switcher widget to the desktop view.

Improving the Speakers List

In the mobile browser, select the **Speakers** link. Because there's no mobile view(*AllSpeakers.Mobile.cshtml*), the default speakers display (*AllSpeakers.cshtml*) is rendered using the mobile layout view (*_Layout.Mobile.cshtml*).

You can globally disable a default (non-mobile) view from rendering inside a mobile layout by setting `RequireConsistentDisplayMode` to `true` in the *Views_ViewStart.cshtml* file, like this:

```
@{
    Layout = "~/Views/Shared/_Layout.cshtml";
    DisplayModeProvider.Instance.RequireConsistentDisplayMode = true;
}
```

When `RequireConsistentDisplayMode` is set to `true`, the mobile layout (*_Layout.Mobile.cshtml*) is used only for mobile views. (That is, the view file is of the form ***ViewName.Mobile.cshtml*.) You might want to set `RequireConsistentDisplayMode` to `true` if your mobile layout doesn't work well with your non-mobile views. The screenshot below shows how the *Speakers* page renders when `RequireConsistentDisplayMode` is set to `true`.

You can disable consistent display mode in a view by setting `RequireConsistentDisplayMode` to `false` in the view file. The following markup in the *Views\Home\AllSpeakers.cshtml* file sets `RequireConsistentDisplayMode` to `false` :

```
@model IEnumerable<string>

@{
    ViewBag.Title = "All speakers";
    DisplayModeProvider.Instance.RequireConsistentDisplayMode = false;
}
```

Creating a Mobile Speakers View

As you just saw, the *Speakers* view is readable, but the links are small and are difficult to tap on a mobile device. In this section, you'll create a mobile-specific *Speakers* view that looks like a modern mobile application — it displays large, easy-to-tap links and contains a search box to quickly find speakers.

Copy *AllSpeakers.cshtml* to *AllSpeakers.Mobile.cshtml*. Open the *AllSpeakers.Mobile.cshtml* file and remove the `<h2>` heading element.

In the `<ul>` tag, add the `data-role` attribute and set its value to `listview`. Like other `data-*` attributes, `data-role="listview"` makes the large list items easier to tap. This is what the completed markup looks like:

```
@model IEnumerable<string>

@{
    ViewBag.Title = "All speakers";
}
<ul data-role="listview">
    @foreach(var speaker in Model) {
        <li>@Html.ActionLink(speaker, "SessionsBySpeaker", new { speaker })</li>
    }
</ul>
```

Refresh the mobile browser. The updated view looks like this:

Although the mobile view has improved, it's difficult to navigate the long list of speakers. To fix this, in the `<ul>` tag, add the `data-filter` attribute and set it to `true`. The code below shows the `ul` markup.

```
<ul data-role="listview" data-filter="true">
```

The following image shows the search filter box at the top of the page that results from the `data-filter` attribute.

As you type each letter in the search box, jQuery Mobile filters the displayed list as shown in the image below.

Improving the Tags List

Like the default *Speakers* view, the *Tags* view is readable, but the links are small and difficult to tap on a mobile device. In this section, you'll fix the *Tags* view the same way you fixed the *Speakers* view.

Remove the "hide" suffix to the *Views\Home\AllTags.Mobile.cshtml.hide* file so the name is *Views\Home\AllTags.Mobile.cshtml*. Open the renamed file and remove the `<h2>` element.

Add the `data-role` and `data-filter` attributes to the `<ul>` tag, as shown here:

```
<ul data-role="listview" data-filter="true">
```

The image below shows the tags page filtering on the letter `J`.

Improving the Dates List

You can improve the *Dates* view like you improved the *Speakers* and *Tags* views, so that it's easier to use on a mobile device.

Copy the *Views\Home\AllDates.cshtml* file to *Views\Home\AllDates.Mobile.cshtml*. Open the new file and remove the `<h2>` element.

Add `data-role="listview"` to the `<ul>` tag, like this:

```
<ul data-role="listview">
```

The image below shows what the **Date** page looks like with the `data-role` attribute in place.

Replace the contents of the *Views\Home\AllDates.Mobile.cshtml* file with the following code:

```
@model IEnumerable<DateTime>
@{
    ViewBag.Title = "All dates";
    DateTime lastDay = default(DateTime);
}
<ul data-role="listview">
    @foreach(var date in Model) {
        if (date.Date != lastDay) {
            lastDay = date.Date;
            <li data-role="list-divider">@date.Date.ToString("ddd, MMM dd")</li>
        }
        <li>@Html.ActionLink(date.ToString("h:mm tt"), "SessionsByDate", new { date })</li>
    }
</ul>
```

This code groups all sessions by days. It creates a list divider for each new day, and it lists all the sessions for each day under a divider. Here's what it looks like when this code runs:

Improving the SessionsTable View

In this section, you'll create a mobile-specific view of sessions. The changes we make will be more extensive than in other views we have created.

In the mobile browser, tap the **Speaker** button, then enter `Sc` in the search box.

Tap the **Scott Hanselman** link.

As you can see, the display is difficult to read on a mobile browser. The date column is hard to read and the tags column is out of the view. To fix this, copy *Views\Home\SessionsTable.cshtml* to *Views\Home\SessionsTable.Mobile.cshtml*, and then replace the contents of the file with the following code:

```
@using MvcMobile.Models
@model IEnumerable<Session>

<ul data-role="listview">
    @foreach(var session in Model) {
        <li>
            <a href="@Url.Action("SessionByCode", new { session.Code })">
                <h3>@session.Title</h3>
                <p><strong>@string.Join(", ", session.Speakers)</strong></p>
                <p>@session.DateText</p>
            </a>
        </li>
    }
</ul>
```

The code removes the room and tags columns, and formats the title, speaker, and date vertically, so that all this information is readable on a mobile browser. The image below reflects the code changes.

Improving the SessionByCode View

Finally, you'll create a mobile-specific view of the *SessionByCode* view. In the mobile browser, tap the **Speaker** button, then enter `Sc` in the search box.

Tap the **Scott Hanselman** link. Scott Hanselman's sessions are displayed.

Choose the **An Overview of the MS Web Stack of Love** link.

The default desktop view is fine, but you can improve it.

Copy the *Views\Home\SessionByCode.cshtml* to *Views\Home\SessionByCode.Mobile.cshtml* and replace the contents of the *Views\Home\SessionByCode.Mobile.cshtml* file with the following markup:

```
@model MvcMobile.Models.Session

@{
    ViewBag.Title = "Session details";
}
<h2>@Model.Title</h2>
<p>
    <strong>@Model.DateText</strong> in <strong>@Model.Room</strong>
</p>

<ul data-role="listview" data-inset="true">
    <li data-role="list-divider">Speakers</li>
    @foreach (var speaker in Model.Speakers) {
        <li>@Html.ActionLink(speaker, "SessionsBySpeaker", new { speaker })</li>
    }
</ul>

<p>@Model.Description</p>
<h4>Code: @Model.Code</h4>

<ul data-role="listview" data-inset="true">
    <li data-role="list-divider">Tags</li>
    @foreach (var tag in Model.Tags) {
        <li>@Html.ActionLink(tag, "SessionsByTag", new { tag })</li>
    }
</ul>
```

The new markup uses the `data-role` attribute to improve the layout of the view.

Refresh the mobile browser. The following image reflects the code changes that you just made:

Wrapup and Review

This tutorial has introduced the new mobile features of ASP.NET MVC 4 Developer Preview. The mobile features include:

- The ability to override layout, views, and partial views, both globally and for an individual view.
- Control over layout and partial override enforcement using the `RequireConsistentDisplayMode` property.
- A view-switcher widget for mobile views than can also be displayed in desktop views.
- Support for supporting specific browsers, such as the iPhone browser.

Using OAuth Providers with MVC 4

2/20/2020 • 15 minutes to read • Edit Online

by Tom FitzMacken

> This tutorial shows you how to build an ASP.NET MVC 4 web application that enables users to log in with credentials from an external provider, such as Facebook, Twitter, Microsoft, or Google, and then integrate some of the functionality from those providers into your web application. For simplicity, this tutorial focuses on working with credentials from Facebook.
>
> To use external credentials in an ASP.NET MVC 5 web application, see Create an ASP.NET MVC 5 App with Facebook and Google OAuth2 and OpenID Sign-on.
>
> Enabling these credentials in your web sites provides a significant advantage because millions of users already have accounts with these external providers. These users may be more inclined to sign up for your site if they do not have to create and remember a new set of credentials. Also, after a user has logged in through one of these providers, you can incorporate social operations from the provider.

What you'll build

There are two main goals in this tutorial:

1. Enable a user to log in with credentials from an OAuth provider.
2. Retrieve account information from the provider and integrate that information with the account registration for your site.

Although the examples in this tutorial focus on using Facebook as the authentication provider, you can modify the code to use any of the providers. The steps to implement any provider are very similar to the steps you will see in this tutorial. You will only notice significant differences when making direct calls to the provider's API set.

Prerequisites

- Microsoft Visual Studio 2012 or Microsoft Visual Studio Express 2012 for Web

Or

- Microsoft Visual Studio 2010 SP1 or Visual Web Developer Express 2010 SP1
- ASP.NET MVC 4

Furthermore, this topic assumes you have basic knowledge about ASP.NET MVC and Visual Studio. If you need an introduction to ASP.NET MVC 4, see Intro to ASP.NET MVC 4.

Create the project

In Visual Studio, create a new ASP.NET MVC 4 Web Application, and name it "OAuthMVC". You can target either .NET Framework 4.5 or 4.

In the New ASP.NET MVC 4 Project window, select **Internet Application** and leave **Razor** as the view engine.

Enable a provider

When you create an MVC 4 web application with the Internet Application template, the project is created with a file named AuthConfig.cs in the App_Start folder.

The AuthConfig file contains code to register clients for external authentication providers. By default, this code is commented out, so none of the external providers are enabled.

```
public static class AuthConfig
{
    public static void RegisterAuth()
    {
        // To let users of this site log in using their accounts from other sites such as Microsoft, Facebook,
and Twitter,
        // you must update this site. For more information visit https://go.microsoft.com/fwlink/?
LinkID=252166

        //OAuthWebSecurity.RegisterMicrosoftClient(
        //    clientId: "",
        //    clientSecret: "");

        //OAuthWebSecurity.RegisterTwitterClient(
        //    consumerKey: "",
        //    consumerSecret: "");

        //OAuthWebSecurity.RegisterFacebookClient(
        //    appId: "",
        //    appSecret: "");

        //OAuthWebSecurity.RegisterGoogleClient();
    }
}
```

You must uncomment this code to use the external authentication client. You uncomment only the providers you want to include in your site. For this tutorial, you will only enable the Facebook credentials.

```
public static class AuthConfig
{
    public static void RegisterAuth()
    {
        //OAuthWebSecurity.RegisterMicrosoftClient(
        //    clientId: "",
        //    clientSecret: "");

        //OAuthWebSecurity.RegisterTwitterClient(
        //    consumerKey: "",
        //    consumerSecret: "");

        OAuthWebSecurity.RegisterFacebookClient(
            appId: "",
            appSecret: "");

        //OAuthWebSecurity.RegisterGoogleClient();
    }
}
```

Notice in the above example that the method includes empty strings for the registration parameters. If you try to run the application now, the application throws an argument exception because empty strings are not allowed for the parameters. To provide valid values, you must register your web site with the external providers, as shown in the next section.

Registering with an external provider

To authenticate users with credentials from an external provider, you must register your web site with the provider. When you register your site, you will receive the parameters (such as key or id, and secret) to include when registering the client. You must have an account with the providers you wish to use.

This tutorial does not show all of the steps you must perform to register with these providers. The steps are typically not difficult. To successfully register your site, follow the instructions provided on those sites. To get started with registering your site, see the developer site for:

- Facebook
- Google
- Microsoft
- Twitter

When registering your site with Facebook, you can provide "localhost" for the site domain and `"http://localhost/"` for the URL, as shown in the image below. Using localhost works with most providers, but currently does not work with the Microsoft provider. For the Microsoft provider, you must include a valid web site URL.

In the previous image, the values for the app id, app secret, and contact email have been removed. When you actually register your site, those values will be present. You will want to note the values for app id and app secret because you will add them to your application.

Creating test users

If you do not mind using an existing Facebook account to test your site, you can skip this section.

You can easily create test users for your application within the Facebook app management page. You can use these test accounts to log in to your site. You create test users by clicking the **Roles** link in the left navigation pane and the clicking the **Create** link.

The Facebook site automatically creates the number of test accounts that you request.

Adding application id and secret from the provider

Now that you have received the id and secret from Facebook, go back to the AuthConfig file and add them as the parameter values. The values shown below are not real values.

```
public static class AuthConfig
{
    public static void RegisterAuth()
    {
        //OAuthWebSecurity.RegisterMicrosoftClient(
        //    clientId: "",
        //    clientSecret: "");

        //OAuthWebSecurity.RegisterTwitterClient(
        //    consumerKey: "",
        //    consumerSecret: "");

        //OAuthWebSecurity.RegisterFacebookClient(
        //    appId: "",
        //    appSecret: "");

        //OAuthWebSecurity.RegisterGoogleClient();
    }
}
```

Log in with external credentials

That is all you have to do to enable external credentials in your site. Run your application and click the login link in the upper right corner. The template automatically recognizes that you have registered Facebook as a provider and includes a button for the provider. If you register multiple providers, a button for each one is automatically included.

This tutorial does not cover how to customize the log in buttons for the external providers. For that information, see Customizing the login UI when using OAuth/OpenID.

Click on the Facebook button to log in with Facebook credentials. When you select one of the external providers, you are redirected to that site and prompted by that service to log in.

The following image shows the login screen for Facebook. It notes that you are using your Facebook account to log in to a site named oauthmvcexample.

After logging in with Facebook credentials, a page informs the user that the site will have access to basic information.

After selecting **Go to App**, the user must register for the site. The following image shows the registration page after a user has logged in with Facebook credentials. The user name is typically pre-filled with a name from the provider.

Click **Register** to complete registration. Close the browser.

You can see that the new account has been added to your database. In Server Explorer, open the **DefaultConnection** database and open the **Tables** folder.

Right-click the **UserProfile** table and select **Show Table Data**.

You will see the new account you added. Look at the data in **webpage_OAuthMembership** table. You will see more data related to the external provider for the account you just added.

If you only want to enable external authentication, you are done. However, you can further integrate information from the provider into the new user registration process, as shown in the following sections.

Create models for additional user information

As you noticed in the previous sections, you do not need to retrieve any additional information for the built-in account registration to work. However, most external providers pass back additional information about the user. The following sections show how to retain that information and save it to a database. Specifically, you will retain values for the user's full name, the URI of the user's personal web page, and a value that indicates whether Facebook has verified the account.

You will use Code First Migrations to add a table for storing additional user information. You are adding the table to an existing database, so you will first need to create a snapshot of the current database. By creating a snapshot of the current database, you can later create a migration that contains only the new table. To create a snapshot of the current database:

1. Open the **Package Manager Console**
2. Run the command **enable-migrations**
3. Run the command **add-migration initial –IgnoreChanges**
4. Run the command **update-database**

Now, you will add the new properties. In the Models folder, open the AccountModels.cs file, and find the RegisterExternalLoginModel class. The RegisterExternalLoginModel class holds values that come back from the authentication provider. Add properties named FullName and Link, as highlighted below.

```
public class RegisterExternalLoginModel
{
    [Required]
    [Display(Name = "User name")]
    public string UserName { get; set; }

    public string ExternalLoginData { get; set; }

    [Display(Name = "Full name")]
    public string FullName { get; set; }

    [Display(Name = "Personal page link")]
    public string Link { get; set; }
}
```

Also in AccountModels.cs, add a new class called ExtraUserInformation. This class represents the new table which will be created in the database.

```
[Table("ExtraUserInformation")]
public class ExternalUserInformation
{
    public int Id { get; set; }
    public int UserId { get; set; }
    public string FullName { get; set; }
    public string Link { get; set; }
    public bool? Verified { get; set; }
}
```

In the UsersContext class, add the highlighted code below to create a DbSet property for the new class.

```
public class UsersContext : DbContext
{
    public UsersContext()
        : base("DefaultConnection")
    {
    }

    public DbSet<UserProfile> UserProfiles { get; set; }
    public DbSet<ExternalUserInformation> ExternalUsers { get; set; }
}
```

You are now ready to create the new table. Open the Package Manager Console again and this time:

1. Run the command **add-migration AddExtraUserInformation**
2. Run the command **update-database**

The new table now exists in the database.

Retrieve the additional data

There are two ways to retrieve additional user data. The first way is to retain user data that is passed back, by default, during the authentication request. The second way is to specifically call the provider API and request more information. Values for FullName and Link are automatically passed back by Facebook. A value that indicates whether Facebook has verified the account is retrieved through a call to the Facebook API. First, you will populate values for FullName and Link, and then later, you will get the verified value.

To retrieve the additional user data, open the **AccountController.cs** file in the **Controllers** folder.

This file contains the logic for logging, registering, and managing accounts. In particular, notice the methods called

ExternalLoginCallback and **ExternalLoginConfirmation**. Within these methods, you can add code to customize external login operations for your application. The first line of the **ExternalLoginCallback** method contains:

```
AuthenticationResult result = OAuthWebSecurity.VerifyAuthentication(
    Url.Action("ExternalLoginCallback", new { ReturnUrl = returnUrl }));
```

Additional user data is passed back in the **ExtraData** property of the **AuthenticationResult** object that is returned from the **VerifyAuthentication** method. The Facebook client contains the following values in the **ExtraData** property:

- id
- name
- link
- gender
- accesstoken

Other providers will have similar but slightly different data in the ExtraData property.

If the user is new to your site, you will retrieve some the additional data and pass that data to the confirmation view. The last block of code in the method is run only if the user is new to your site. Replace the following line:

```
return View("ExternalLoginConfirmation", new RegisterExternalLoginModel
{
    UserName = result.UserName,
    ExternalLoginData = loginData
});
```

With this line:

```
return View("ExternalLoginConfirmation", new RegisterExternalLoginModel
{
    UserName = result.UserName,
    ExternalLoginData = loginData,
    FullName = result.ExtraData["name"],
    Link = result.ExtraData["link"]
});
```

This change merely includes values for the FullName and Link properties.

In the **ExternalLoginConfirmation** method, modify the code as highlighted below to save the additional user information.

```
if (user == null)
{
    // Insert name into the profile table
    UserProfile newUser = db.UserProfiles.Add(new UserProfile { UserName = model.UserName });
    db.SaveChanges();

    db.ExternalUsers.Add(new ExternalUserInformation
    {
        UserId = newUser.UserId,
        FullName = model.FullName,
        Link = model.Link
    });
    db.SaveChanges();

    OAuthWebSecurity.CreateOrUpdateAccount(provider, providerUserId, model.UserName);
    OAuthWebSecurity.Login(provider, providerUserId, createPersistentCookie: false);

    return RedirectToLocal(returnUrl);
}
else
{
    ModelState.AddModelError("UserName", "User name already exists. Please enter a different user name.");
}
```

Adjusting the view

The additional user data that you retrieve from the provider will be displayed in the registration page.

In the **Views/Account** folder, open **ExternalLoginConfirmation.cshtml**. Below the existing field for user name, add fields for FullName, Link, and PictureLink.

```
<li>
    @Html.LabelFor(m => m.FullName)
    @Html.TextBoxFor(m => m.FullName)
</li>
<li>
    @Html.LabelFor(m => m.Link)
    @Html.TextBoxFor(m => m.Link)
</li>
```

You are now almost ready to run the application and register a new user with the additional information saved. You must have an account that is not already registered with the site. You can either use a different test account, or delete the rows in the **UserProfile** and **webpages_OAuthMembership** tables for the account you wish to reuse. By deleting those rows, you will ensure that the account is registered again.

Run the application and register the new user. Notice that this time the confirmation page contains more values.

After completing registration, close the browser. Look in the database to notice the new values in the **ExtraUserInformation** table.

Install NuGet package for Facebook API

Facebook provides an API that you can call to perform operations. You can call the Facebook API either by directing sending HTTP requests, or by using installing a NuGet package that facilitates sending those requests. Using a NuGet package is shown in this tutorial, but installing NuGet package is not essential. This tutorial shows how to use the Facebook C# SDK package. There are other NuGet packages that assist with calling the Facebook API.

From the **Manage NuGet Packages** windows, select the Facebook C# SDK package.

You will use the Facebook C# SDK to call an operation that requires the access token for the user. The next section shows how to get the access token.

Retrieve access token

Most external providers pass back an access token after the user's credentials are verified. This access token is very important because it enables you to call operations that are only available to authenticated users. Therefore, retrieving and storing the access token is essential when you want to provide more functionality.

Depending on the external provider, the access token may be valid for only a limited amount of time. To ensure that you have a valid access token, you will retrieve it each time the user logs in, and store it as a session value rather than save it to a database.

In the **ExternalLoginCallback** method, the access token is also passed back in the **ExtraData** property of the **AuthenticationResult** object. Add the highlighted code to **ExternalLoginCallback** to save the access token in the **Session** object. This code is run every time the user logs in with a Facebook account.

```
[AllowAnonymous]
public ActionResult ExternalLoginCallback(string returnUrl)
{
    AuthenticationResult result = OAuthWebSecurity.VerifyAuthentication(
        Url.Action("ExternalLoginCallback", new { ReturnUrl = returnUrl }));
    if (!result.IsSuccessful)
    {
        return RedirectToAction("ExternalLoginFailure");
    }

    if (result.ExtraData.Keys.Contains("accesstoken"))
    {
        Session["facebooktoken"] = result.ExtraData["accesstoken"];
    }

    if (OAuthWebSecurity.Login(
        result.Provider,
        result.ProviderUserId,
        createPersistentCookie: false))
    {
        return RedirectToLocal(returnUrl);
    }

    if (User.Identity.IsAuthenticated)
    {
        // If the current user is logged in add the new account
        OAuthWebSecurity.CreateOrUpdateAccount(
            result.Provider,
            result.ProviderUserId,
            User.Identity.Name);
        return RedirectToLocal(returnUrl);
    }
    else
    {
        // User is new, ask for their desired membership name
        string loginData = OAuthWebSecurity.SerializeProviderUserId(
            result.Provider,
            result.ProviderUserId);
        ViewBag.ProviderDisplayName =
            OAuthWebSecurity.GetOAuthClientData(result.Provider).DisplayName;
        ViewBag.ReturnUrl = returnUrl;
        return View("ExternalLoginConfirmation", new RegisterExternalLoginModel
        {
            UserName = result.UserName,
            ExternalLoginData = loginData,
            FullName = result.ExtraData["name"],
            Link = result.ExtraData["link"]
        });
    }
}
```

Although this example retrieves an access token from Facebook, you can retrieve the access token from any external provider through the same key named "accesstoken".

Logging off

The default **LogOff** method logs the user out of your application, but does not log the user out of the external provider. To log the user out of Facebook, and prevent the token from persisting after the user has logged off, you can add the following highlighted code to the **LogOff** method in the AccountController.

```
[HttpPost]
[ValidateAntiForgeryToken]
public ActionResult LogOff()
{
    WebSecurity.Logout();
    if (Session["facebooktoken"] != null)
    {
        var fb = new Facebook.FacebookClient();
        string accessToken = Session["facebooktoken"] as string;
        var logoutUrl = fb.GetLogoutUrl(new { access_token = accessToken, next = "http://localhost:39852/" });

        Session.RemoveAll();
        return Redirect(logoutUrl.AbsoluteUri);
    }

    return RedirectToAction("Index", "Home");
}
```

The value you provide in the `next` parameter is the URL to use after the user has logged out of Facebook. When testing on your local computer, you would provide the correct port number for your local site. In production, you would provide a default page, such as contoso.com.

Retrieve user information that requires the access token

Now that you have stored the access token and installed the Facebook C# SDK package, you can use them together to request additional user information from Facebook. In the **ExternalLoginConfirmation** method, create an instance of the **FacebookClient** class by passing the value of the access token. Request the value of the **verified** property for the current, authenticated user. The **verified** property indicates whether Facebook has validated the account through some other means, such as sending a message to a cell phone. Save this value in the database.

```
if (user == null)
{
    // Insert name into the profile table
    UserProfile newUser = db.UserProfiles.Add(new UserProfile { UserName = model.UserName });
    db.SaveChanges();

    bool facebookVerified;

    var client = new Facebook.FacebookClient(Session["facebooktoken"].ToString());
    dynamic response = client.Get("me", new { fields = "verified" });
    if (response.ContainsKey("verified"))
    {
        facebookVerified = response["verified"];
    }
    else
    {
        facebookVerified = false;
    }

    db.ExternalUsers.Add(new ExternalUserInformation
    {
        UserId = newUser.UserId,
        FullName = model.FullName,
        Link = model.Link,
        Verified = facebookVerified
    });
    db.SaveChanges();

    OAuthWebSecurity.CreateOrUpdateAccount(provider, providerUserId, model.UserName);
    OAuthWebSecurity.Login(provider, providerUserId, createPersistentCookie: false);

    return RedirectToLocal(returnUrl);
}
```

You will again need to either delete the records in the database for the user, or use a different Facebook account.

Run the application, and register the new user. Look at the **ExtraUserInformation** table to see the value for the Verified property.

Conclusion

In this tutorial, you created a site that is integrated with Facebook for user authentication and registration data. You learned about the default behavior that is set up for MVC 4 web application, and how to customize that default behavior.

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

What You'll Build

You'll implement a simple movie-listing application that supports creating, editing, and listing movies from a database. Below are two screenshots of the application you'll build. It includes a page that displays a list of movies from a database:

The application also lets you add, edit, and delete movies, as well as see details about individual ones. All data-entry scenarios include validation to ensure that the data stored in the database is correct.

Skills You'll Learn

Here's what you'll learn:

- How to create a new ASP.NET MVC project.
- How to create ASP.NET MVC controllers and views.
- How to create a new database using the Entity Framework Code First paradigm.
- How to retrieve and display data.
- How to edit data and enable data validation.

Getting Started

Start by running Visual Web Developer 2010 Express ("Visual Web Developer" for short) and select **New Project** from the **Start** page.

Visual Web Developer is an IDE, or integrated development environment. Just like you use Microsoft Word to write documents, you'll use an IDE to create applications. In Visual Web Developer there's a toolbar along the top showing various options available to you. There's also a menu that provides another way to perform tasks in the IDE. (For example, instead of selecting **New Project** from the **Start** page, you can use the menu and select **File** > **New Project**.)

Creating Your First Application

You can create applications using either Visual Basic or Visual C# as the programming language. Select Visual C# on the left and then select **ASP.NET MVC 3 Web Application**. Name your project "MvcMovie" and then click **OK**. (If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.)

In the **New ASP.NET MVC 3 Project** dialog box, select **Internet Application**. Check **Use HTML5 markup** and leave **Razor** as the default view engine.

Click **OK**. Visual Web Developer used a default template for the ASP.NET MVC project you just created, so you have a working application right now without doing anything! This is a simple "Hello World!" project, and it's a good place to start your application.

From the **Debug** menu, select **Start Debugging**.

Notice that the keyboard shortcut to start debugging is F5.

F5 causes Visual Web Developer to start a development web server and run your web application. Visual Web Developer then launches a browser and opens the application's home page. Notice that the address bar of the browser says `localhost` and not something like `example.com`. That's because `localhost` always points to your own local computer, which in this case is running the application you just built. When Visual Web Developer runs a web project, a random port is used for the web server. In the image below, the random port number is 43246. When you run the application, you'll probably see a different port number.

Right out of the box this default template gives you two pages to visit and a basic login page. The next step is to change how this application works and learn a little bit about ASP.NET MVC in the process. Close your browser and let's change some code.

Adding a Controller (C#)

2/20/2020 • 4 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

MVC stands for *model-view-controller*. MVC is a pattern for developing applications that are well architected and easy to maintain. MVC-based applications contain:

- Controllers: Classes that handle incoming requests to the application, retrieve model data, and then specify view templates that return a response to the client.
- Models: Classes that represent the data of the application and that use validation logic to enforce business rules for that data.
- Views: Template files that your application uses to dynamically generate HTML responses.

We'll be covering all these concepts in this tutorial series and show you how to use them to build an application.

Let's begin by creating a controller class. In **Solution Explorer**, right-click the *Controllers* folder and then select **Add Controller**.

Name your new controller "HelloWorldController". Leave the default template as **Empty controller** and click **Add**.

Notice in **Solution Explorer** that a new file has been created named *HelloWorldController.cs*. The file is open in the IDE.

Inside the `public class HelloWorldController` block, create two methods that look like the following code. The controller will return a string of HTML as an example.

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        //
        // GET: /HelloWorld/

        public string Index()
        {
            return "This is my <b>default</b> action...";
        }

        //
        // GET: /HelloWorld/Welcome/

        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Your controller is named `HelloWorldController` and the first method above is named `Index`. Let's invoke it from a browser. Run the application (press F5 or Ctrl+F5). In the browser, append "HelloWorld" to the path in the address bar. (For example, in the illustration below, it's `http://localhost:43246/HelloWorld.`) The page in the browser will look like the following screenshot. In the method above, the code returned a string directly. You told the system to just return some HTML, and it did!

ASP.NET MVC invokes different controller classes (and different action methods within them) depending on the incoming URL. The default mapping logic used by ASP.NET MVC uses a format like this to determine what code to invoke:

```
/[Controller]/[ActionName]/[Parameters]
```

The first part of the URL determines the controller class to execute. So */HelloWorld* maps to the `HelloWorldController` class. The second part of the URL determines the action method on the class to execute. So */HelloWorld/Index* would cause the `Index` method of the `HelloWorldController` class to execute. Notice that we only had to browse to */HelloWorld* and the `Index` method was used by default. This is because a method named `Index` is the default method that will be called on a controller if one is not explicitly specified.

Browse to `http://localhost:xxxx/HelloWorld/Welcome`. The `Welcome` method runs and returns the string "This is the Welcome action method...". The default MVC mapping is `/[Controller]/[ActionName]/[Parameters]`. For this URL, the controller is `HelloWorld` and `Welcome` is the action method. You haven't used the `[Parameters]` part of the URL yet.

Let's modify the example slightly so that you can pass some parameter information from the URL to the controller (for example, */HelloWorld/Welcome?name=Scott&numtimes=4*). Change your `Welcome` method to include two parameters as shown below. Note that the code uses the C# optional-parameter feature to indicate that the `numTimes` parameter should default to 1 if no value is passed for that parameter.

```
public string Welcome(string name, int numTimes = 1) {
     return HttpUtility.HtmlEncode("Hello " + name + ", NumTimes is: " + numTimes);
}
```

Run your application and browse to the example URL (`http://localhost:xxxx/HelloWorld/Welcome?name=Scott&numtimes=4)` . You can try different values for `name` and `numtimes` in the URL. The system automatically maps the named parameters from the query string in the address bar to parameters in your method.

In both these examples the controller has been doing the "VC" portion of MVC — that is, the view and controller work. The controller is returning HTML directly. Ordinarily you don't want controllers returning HTML directly, since that becomes very cumbersome to code. Instead we'll typically use a separate view template file to help generate the HTML response. Let's look next at how we can do this.

Adding a View (C#)

2/20/2020 • 8 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this section you're going to modify the `HelloWorldController` class to use view template files to cleanly encapsulate the process of generating HTML responses to a client.

You'll create a view template file using the new Razor view engine introduced with ASP.NET MVC 3. Razor-based view templates have a *.cshtml* file extension, and provide an elegant way to create HTML output using C#. Razor minimizes the number of characters and keystrokes required when writing a view template, and enables a fast, fluid coding workflow.

Start by using a view template with the `Index` method in the `HelloWorldController` class. Currently the `Index` method returns a string with a message that is hard-coded in the controller class. Change the `Index` method to return a `View` object, as shown in the following:

```
public ActionResult Index()
{
    return View();
}
```

This code uses a view template to generate an HTML response to the browser. In the project, add a view template that you can use with the `Index` method. To do this, right-click inside the `Index` method and click **Add View**.

```
public class HelloWorldController : Controller
{
    public ActionResult Index
    {
        return View();
    }
```

The **Add View** dialog box appears. Leave the defaults the way they are and click the **Add** button:

The *MvcMovie\Views\HelloWorld* folder and the *MvcMovie\Views\HelloWorld\Index.cshtml* file are created. You can see them in **Solution Explorer**:

The following shows the *Index.cshtml* file that was created:

Add some HTML under the `<h2>` tag. The modified *MvcMovie\Views\HelloWorld\Index.cshtml* file is shown below.

```
@{
    ViewBag.Title = "Index";
}

<h2>Index</h2>

<p>Hello from our View Template!</p>
```

Run the application and browse to the `HelloWorld` controller (`http://localhost:xxxx/HelloWorld`). The `Index` method in your controller didn't do much work; it simply ran the statement `return View()`, which specified that the method should use a view template file to render a response to the browser. Because you didn't explicitly specify the name of the view template file to use, ASP.NET MVC defaulted to using the *Index.cshtml* view file in the *\Views\HelloWorld* folder. The image below shows the string hard-coded in the view.

Looks pretty good. However, notice that the browser's title bar says "Index" and the big title on the page says "My MVC Application." Let's change those.

Changing Views and Layout Pages

First, you want to change the "My MVC Application" title at the top of the page. That text is common to every page. It actually is implemented in only one place in the project, even though it appears on every page in the application. Go to the */Views/Shared* folder in **Solution Explorer** and open the *_Layout.cshtml* file. This file is called a *layout page* and it's the shared "shell" that all other pages use.

Layout templates allow you to specify the HTML container layout of your site in one place and then apply it across multiple pages in your site. Note the `@RenderBody()` line near the bottom of the file. `RenderBody` is a placeholder where all the view-specific pages you create show up, "wrapped" in the layout page. Change the title heading in the layout template from "My MVC Application" to "MVC Movie App".

```
<div id="title">
      <h1>MVC Movie App</h1>
  </div>
```

Run the application and notice that it now says "MVC Movie App". Click the **About** link, and you see how that page shows "MVC Movie App", too. We were able to make the change once in the layout template and have all pages on the site reflect the new title.

The complete *_Layout.cshtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>@ViewBag.Title</title>
    <link href="@Url.Content("~/Content/Site.css")" rel="stylesheet" type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.5.1.min.js")" type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/modernizr-1.7.min.js")" type="text/javascript"></script>
</head>
<body>
    <div class="page">
        <header>
            <div id="title">
                <h1>MVC Movie App</h1>
            </div>
            <div id="logindisplay">
                @Html.Partial("_LogOnPartial")
            </div>
            <nav>
                <ul id="menu">
                    <li>@Html.ActionLink("Home", "Index", "Home")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                </ul>
            </nav>
        </header>
        <section id="main">
            @RenderBody()
        </section>
        <footer>
        </footer>
    </div>
</body>
</html>
```

Now, let's change the title of the Index page (view).

Open *MvcMovie\Views\HelloWorld\Index.cshtml*. There are two places to make a change: first, the text that appears in the title of the browser, and then in the secondary header (the `<h2>` element). You'll make them slightly different so you can see which bit of code changes which part of the app.

```
@{
    ViewBag.Title = "Movie List";
}

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

To indicate the HTML title to display, the code above sets a `Title` property of the `ViewBag` object (which is in the *Index.cshtml* view template). If you look back at the source code of the layout template, you'll notice that the template uses this value in the `<title>` element as part of the `<head>` section of the HTML. Using this approach, you can easily pass other parameters between your view template and your layout file.

Run the application and browse to `http://localhost:xx/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.)

Also notice how the content in the *Index.cshtml* view template was merged with the *_Layout.cshtml* view template and a single HTML response was sent to the browser. Layout templates make it really easy to make changes that apply across all of the pages in your application.

Our little bit of "data" (in this case the "Hello from our View Template!" message) is hard-coded, though. The MVC application has a "V" (view) and you've got a "C" (controller), but no "M" (model) yet. Shortly, we'll walk through how create a database and retrieve model data from it.

Passing Data from the Controller to the View

Before we go to a database and talk about models, though, let's first talk about passing information from the controller to a view. Controller classes are invoked in response to an incoming URL request. A controller class is where you write the code that handles the incoming parameters, retrieves data from a database, and ultimately decides what type of response to send back to the browser. View templates can then be used from a controller to generate and format an HTML response to the browser.

Controllers are responsible for providing whatever data or objects are required in order for a view template to render a response to the browser. A view template should never perform business logic or interact with a database directly. Instead, it should work only with the data that's provided to it by the controller. Maintaining this "separation of concerns" helps keep your code clean and more maintainable.

Currently, the `Welcome` action method in the `HelloWorldController` class takes a `name` and a `numTimes` parameter and then outputs the values directly to the browser. Rather than have the controller render this response as a string, let's change the controller to use a view template instead. The view template will generate a dynamic response, which means that you need to pass appropriate bits of data from the controller to the view in order to generate the response. You can do this by having the controller put the dynamic data that the view template needs in a `ViewBag` object that the view template can then access.

Return to the *HelloWorldController.cs* file and change the `Welcome` method to add a `Message` and `NumTimes` value to the `ViewBag` object. `ViewBag` is a dynamic object, which means you can put whatever you want in to it; the `ViewBag` object has no defined properties until you put something inside it. The complete *HelloWorldController.cs* file looks like this:

```
using System.Web;
using System.Web.Mvc;

namespace MvcMovie.Controllers
{
    public class HelloWorldController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult Welcome(string name, int numTimes = 1)
        {
            ViewBag.Message = "Hello " + name;
            ViewBag.NumTimes = numTimes;

            return View();
        }
    }
}
```

Now the `ViewBag` object contains data that will be passed to the view automatically.

Next, you need a Welcome view template! In the **Debug** menu, select **Build MvcMovie** to make sure the project is compiled.

Then right-click inside the `Welcome` method and click **Add View**. Here's what the **Add View** dialog box looks like:

Click **Add**, and then add the following code under the `<h2>` element in the new *Welcome.cshtml* file. You'll create a loop that says "Hello" as many times as the user says it should. The complete *Welcome.cshtml* file is shown below.

```
@{
    ViewBag.Title = "Welcome";
}

<h2>Welcome</h2>

<ul>
   @for (int i=0; i < ViewBag.NumTimes; i++) {
      <li>@ViewBag.Message</li>
   }
</ul>
```

Run the application and browse to the following URL:

`http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4`

Now data is taken from the URL and passed to the controller automatically. The controller packages the data into a `ViewBag` object and passes that object to the view. The view then displays the data as HTML to the user.

Well, that was a kind of an "M" for model, but not the database kind. Let's take what we've learned and create a database of movies.

PREVIOUS NEXT

Adding a Model (C#)

2/20/2020 • 3 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

Adding a Model

In this section you'll add some classes for managing movies in a database. These classes will be the "model" part of the ASP.NET MVC application.

You'll use a .NET Framework data-access technology known as the Entity Framework to define and work with these model classes. The Entity Framework (often referred to as EF) supports a development paradigm called *Code First*. Code First allows you to create model objects by writing simple classes. (These are also known as POCO classes, from "plain-old CLR objects.") You can then have the database created on the fly from your classes, which enables a very clean and rapid development workflow.

Adding Model Classes

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Name the *class* "Movie".

Add the following five properties to the `Movie` class:

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
}
```

We'll use the `Movie` class to represent movies in a database. Each instance of a `Movie` object will correspond to a row within a database table, and each property of the `Movie` class will map to a column in the table.

In the same file, add the following `MovieDBContext` class:

```
public class MovieDBContext : DbContext
{
    public DbSet<Movie> Movies { get; set; }
}
```

The `MovieDBContext` class represents the Entity Framework movie database context, which handles fetching, storing, and updating `Movie` class instances in a database. The `MovieDBContext` derives from the `DbContext` base class provided by the Entity Framework. For more information about `DbContext` and `DbSet`, see Productivity Improvements for the Entity Framework.

In order to be able to reference `DbContext` and `DbSet`, you need to add the following `using` statement at the top of the file:

```
using System.Data.Entity;
```

The complete *Movie.cs* file is shown below.

```
using System;
using System.Data.Entity;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }
        public string Title { get; set; }
        public DateTime ReleaseDate { get; set; }
        public string Genre { get; set; }
        public decimal Price { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

Creating a Connection String and Working with SQL Server Compact

The `MovieDBContext` class you created handles the task of connecting to the database and mapping `Movie` objects to database records. One question you might ask, though, is how to specify which database it will connect to. You'll do that by adding connection information in the *Web.config* file of the application.

Open the application root *Web.config* file. (Not the *Web.config* file in the *Views* folder.) The image below show both *Web.config* files; open the *Web.config* file circled in red.

Add the following connection string to the `<connectionStrings>` element in the *Web.config* file.

```
<add name="MovieDBContext"
         connectionString="Data Source=|DataDirectory|Movies.sdf"
         providerName="System.Data.SqlServerCe.4.0"/>
```

The following example shows a portion of the *Web.config* file with the new connection string added:

```
<configuration>
  <connectionStrings>
    <add name="MovieDBContext"
         connectionString="Data Source=|DataDirectory|Movies.sdf"
         providerName="System.Data.SqlServerCe.4.0"/>
    <add name="ApplicationServices"
         connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
         providerName="System.Data.SqlClient" />
  </connectionStrings>
```

This small amount of code and XML is everything you need to write in order to represent and store the movie data in a database.

Next, you'll build a new `MoviesController` class that you can use to display the movie data and allow users to create new movie listings.

Accessing your Model's Data from a Controller (C#)

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this section, you'll create a new `MoviesController` class and write code that retrieves the movie data and displays it in the browser using a view template. Be sure to build your application before proceeding.

Right-click the *Controllers* folder and create a new `MoviesController` controller. Select the following options:

- Controller name: **MoviesController**. (This is the default.)
- Template: **Controller with read/write actions and views, using Entity Framework**.
- Model class: **Movie (MvcMovie.Models)**.
- Data context class: **MovieDBContext (MvcMovie.Models)**.
- Views: **Razor (CSHTML)**. (The default.)

Click **Add**. Visual Web Developer creates the following files and folders:

- *A MoviesController.cs* file in the project's *Controllers* folder.
- A *Movies* folder in the project's *Views* folder.
- *Create.cshtml, Delete.cshtml, Details.cshtml, Edit.cshtml*, and *Index.cshtml* in the new *Views\Movies* folder.

The ASP.NET MVC 3 scaffolding mechanism automatically created the CRUD (create, read, update, and delete) action methods and views for you. You now have a fully functional web application that lets you create, list, edit, and delete movie entries.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Because the application is relying on the default routing (defined in the *Global.asax* file), the browser request `http://localhost:xxxxx/Movies` is routed to the default `Index` action method of the `Movies` controller. In other words, the browser request `http://localhost:xxxxx/Movies` is effectively the same as the browser request `http://localhost:xxxxx/Movies/Index`. The result is an empty list of movies, because you haven't added any yet.

Creating a Movie

Select the **Create New** link. Enter some details about a movie and then click the **Create** button.

Clicking the **Create** button causes the form to be posted to the server, where the movie information is saved in the database. You're then redirected to the */Movies* URL, where you can see the newly created movie in the listing.

Create a couple more movie entries. Try the **Edit**, **Details**, and **Delete** links, which are all functional.

Examining the Generated Code

Open the *Controllers\MoviesController.cs* file and examine the generated `Index` method. A portion of the movie controller with the `Index` method is shown below.

```
public class MoviesController : Controller
{
    private MovieDBContext db = new MovieDBContext();

    //
    // GET: /Movies/

    public ViewResult Index()
    {
        return View(db.Movies.ToList());
    }
```

The following line from the `MoviesController` class instantiates a movie database context, as described previously. You can use the movie database context to query, edit, and delete movies.

```
private MovieDBContext db = new MovieDBContext();
```
